Summary (284/300 words)

Background Combining the glucagon-like peptide-1 analogue semaglutide with the long-acting amylin analogue cagrilintide has weight-loss benefits; the impact on glycated haemoglobin is unknown. This trial assessed the efficacy and safety of co-administered semaglutide with cagrilintide (CagriSema) in participants with type 2 diabetes.

Methods This 32-week, multicentre, double-blind, phase 2a trial randomised 92 adults with type 2 diabetes and body-mass index \geq 27 kg/m² on metformin ± sodium-glucose cotransporter-2 inhibitor to once-weekly subcutaneous CagriSema, semaglutide, or cagrilintide (all escalated to 2·4 mg). The primary endpoint was change from baseline in glycated haemoglobin; key secondary endpoints were bodyweight, continuous glucose monitoring (CGM) parameters, and safety. This trial is registered on ClinicalTrials.gov (NCT04982575).

Findings Between August 2, 2021 and October 18, 2021, 92 participants were randomised to CagriSema (N=31), semaglutide (N=31), or cagrilintide (N=30). The mean change in glycated haemoglobin (percentage points) from baseline to week 32 (CagriSema: $-2 \cdot 2$; semaglutide: $-1 \cdot 8$; cagrilintide: $-0 \cdot 9$) was greater with CagriSema versus cagrilintide (estimated treatment difference [95% CI] $-1 \cdot 3$ [$-1 \cdot 7$ to $-0 \cdot 8$]; p<0.001), but not versus semaglutide ($-0 \cdot 4$ [$-0 \cdot 8$ to $0 \cdot 0$]; p=0.07). The mean change in bodyweight from baseline to week 32 (CagriSema: $-15 \cdot 6\%$; semaglutide: $-5 \cdot 1\%$; cagrilintide: $-8 \cdot 1\%$) was greater with CagriSema versus both semaglutide (p<0.001) and cagrilintide (p<0.001). Time in range ($3 \cdot 9 - 10 \cdot 0 \text{ mmol/L}$) was $45 \cdot 9\%$, $32 \cdot 6\%$, and $56 \cdot 9\%$ at baseline and $88 \cdot 9\%$, $76 \cdot 2\%$, and $71 \cdot 7\%$ at week 32 with CagriSema, semaglutide, and cagrilintide, respectively. Mild/moderate gastrointestinal adverse events were most common; no level 2 or 3 hypoglycaemia was reported.

Interpretation In people with type 2 diabetes, treatment with CagriSema resulted in clinically relevant improvements in glycaemic control (including CGM parameters), significantly greater weight loss versus semaglutide and cagrilintide, and was well tolerated.

Funding Funded by Novo Nordisk A/S.

Research in context

Evidence before this study

We searched PubMed for studies in any language published between July 29, 2011, and July 29, 2021, using the search terms ("semaglutide" OR "glucagon-like peptide-1 receptor agonist" OR "GLP-1") AND ("cagrilintide" or "amylin analog"). One phase 1b clinical trial investigating the therapeutic combination of these mechanisms was identified. Individuals with BMI of 27·0-39·9 kg/m² received ascending doses of cagrilinitide (amylin analog) or matched placebo, in combination with semaglutide (GLP-1) 2·4 mg. The combination was well-tolerated with an acceptable safety profile. Mean percentage bodyweight reductions at week 20 were greater with cagrilintide doses of 1·2 mg, 2·4 mg, and 4·5 mg than with placebo. Cagrilintide is an investigational therapy that reduced bodyweight in a phase 2 trial when administered as monotherapy in participants without diabetes and with a body-mass index of at least 30 kg/m², or at least 27 kg/m² with hypertension or dyslipidaemia. Semaglutide is approved for the treatment of type 2 diabetes, for reducing the risk of major adverse cardiovascular events in people with type 2 diabetes and established cardiovascular disease, and for chronic weight management in adults with obesity, or overweight with weight-related comorbidities.

Added value of this study

Our phase 2 clinical trial is the first study to report efficacy and safety data for treatment with the combination of a glucagon-like peptide-1 receptor agonist and an amylin analog in participants with type 2 diabetes. We found that treatment with co-administered semaglutide 2.4 mg and cagrilintide 2.4 mg (CagriSema) resulted in clinically relevant improvements in glycemic control, including continuous glucose monitoring parameters, as well as significantly greater weight loss than either semaglutide or cagrilinitide alone. The magnitude of the weight loss was greater than previously reported with pharmacotherapies in this population. The combination was well tolerated; the most common adverse events were mild or moderate gastrointestinal events.

Implications of all the available evidence

These data support further investigation of CagriSema in this population in longer and larger phase 3 studies.

Introduction

Approximately 90% of adults with type 2 diabetes have overweight or obesity.¹ In addition to the achievement of glycaemic targets and cardiorenal risk reduction, weight loss between 5 to 15% is an appropriate target for many people with type 2 diabetes.²⁻⁶ Weight loss has benefits beyond glycated haemoglobin reduction, including improvements in other metabolic (eg, insulin resistance, hypertension, and hyperlipidaemia), biomechanical, and psychosocial complications.²⁻⁶ In people with type 2 diabetes, sustained weight loss of 10–15% can have disease-modifying effects, including the potential to improve metabolic health, and may reduce the risk of long-term complications.^{2,4,5}

The glucagon-like peptide-1 analogue, semaglutide, is approved as a once-weekly subcutaneous injection (0.5 mg, 1.0 mg, or 2.0 mg) for the treatment of type 2 diabetes (as an adjunct to diet and exercise)⁷ and for reducing the risk of major adverse cardiovascular events in people with type 2 diabetes and established cardiovascular disease.⁸ Subcutaneous semaglutide (2.4 mg) is also approved for chronic weight management as an adjunct to diet and exercise for adults with obesity, or overweight with weight-related comorbidities.^{9,10}

Amylin is a pancreatic beta cell hormone co-secreted with insulin in response to nutrient intake.¹¹ Through activation of neurons in the brain, amylin slows gastric emptying and induces satiety.¹¹⁻¹⁴ Cagrilintide is the first long-acting amylin analogue being investigated for weight management, as a once-weekly treatment in combination with semaglutide.^{13,14} In a phase 2 dose finding trial in people with overweight or obesity and hypertension or dyslipidaemia, and without type 2 diabetes, cagrilintide 2·4 mg, as an adjunct to diet and exercise, resulted in a bodyweight reduction of 10% versus 3% with placebo after 26 weeks.¹³ Furthermore, a phase 1b trial investigating doses of cagrilintide up to 4·5 mg co-administered with semaglutide 2·4 mg in people with overweight or obesity reported a mean bodyweight reduction of 17·1% with cagrilintide 2·4 mg and semaglutide 2·4 mg versus 9·8% with co-administered semaglutide 2·4 mg and placebo after 20 weeks.¹⁴ Thus, combining these agents with different but complementary mechanisms of action has the potential to increase efficacy. It was, therefore, deemed relevant to investigate whether once-weekly subcutaneous co-administration of semaglutide and cagrilintide (both escalated to 2·4 mg) improves glycaemic and weight control, when compared with cagrilintide or semaglutide alone in people with type 2 diabetes and overweight or obesity.

Methods

Study design

This 32-week, multicentre, randomised, double-blind, parallel-group, active-controlled, phase 2 trial was conducted across 17 sites in the United States from August 2021 to July 2022. The trial protocol was approved by appropriate health authorities according to local guidelines and by an Institutional Review Board/Independent Ethics Committee, and was conducted in accordance with the Declaration of Helsinki and International Council on Harmonisation Good Clinical Practice guidelines. Participants provided written informed consent prior to commencement of any trial-related activity. The trial is registered with ClinicalTrials.gov (identifier NCT04982575).

Participants

Adults with type 2 diabetes were eligible for participation if they had a body-mass index $\geq 27 \cdot 0 \text{ kg/m}^2$ and glycated haemoglobin between 7.5 and 10.0% (53–86 mmol/mol), despite being treated with a stable daily dose of metformin with or without a sodium-glucose cotransporter-2 inhibitor for ≥ 90 days prior to screening. Exclusion criteria included renal impairment (estimated glomerular filtration rate <60 mL/min/1.73 m²) and uncontrolled and potentially unstable diabetic retinopathy or maculopathy verified by a fundus examination performed within 90 days prior to screening. Full inclusion and exclusion criteria can be found in the appendix (p 5).

Randomisation and masking

Following a 2-week screening period, eligible participants were randomised 1:1:1 using a web-based randomisation system to receive separate subcutaneous injections of semaglutide 2·4 mg (PDS290 pre-filled pen-injector) and cagrilintide 2·4 mg (NovoPen Echo[®]), hereby referred to as CagriSema, or semaglutide 2·4 mg (PDS290) and cagrilintide placebo (NovoPen Echo), or cagrilintide 2·4 mg (NovoPen Echo[®]) and semaglutide placebo (PDS290) (appendix p 14). Randomisation was stratified according to use of sodium-glucose cotransporter-2 inhibitor treatment (yes/no). The semaglutide 2.4 mg and cagrilintide 2.4 mg trial products were identical to the corresponding placebo in appearance, enabling blinding of treatment. The trial participants, investigators and trial sponsor staff remained blinded throughout the trial.

Procedures

All participants received treatment once weekly for 32 weeks, and treatment allocation remained blinded to the participants and investigators during the entire trial. Treatment doses were escalated every 4 weeks from 0.25 mg to 0.5 mg, 1.0 mg, and 1.7 mg until the maintenance dose of 2.4 mg was reached after 16 weeks. Participants then underwent a 16-week maintenance period, followed by a 5-week follow-up period. Rescue medication was offered if fasting plasma glucose exceeded the predefined limits (15.0 mmol/L [270 mg/dL] from randomisation to week 8; 13.3 mmol/L [240 mg/dL] from week 9 to week 20; 11.1 mmol/L [200 mg/dL] from week 21 to end of treatment). Participants were provided with a Dexcom G6[®] device for collecting continuous glucose monitoring (CGM) profiles, which was to be worn for 10 full days preceding baseline, week 20, and week 32. CGM readings were blinded to both the participant and investigator and were not used for any dose adjustments or hypoglycaemic episode reporting. Mean glucose, as measured by CGM, was based upon measurements taken every 5 minutes. All participants were provided with glucometers, to measure blood glucose if symptoms of hypoglycaemia occurred. Participants experiencing symptoms of hypoglycaemia were instructed to measure blood glucose on their glucometer every 15 minutes until blood glucose was ≥ 3.9 mmol/mol (≥ 70 mg/dL) and/or symptoms had resolved. Hypoglycaemic episodes were recorded in the electronic case report form and participant diaries. Hypoglycaemic episodes were defined according to the American Diabetes Association (ADA) 2018 classification¹⁵ as level 1 (alert value; blood glucose <3.9 mmol/L [<70 mg/dL] and $\ge 3.0 \text{ mmol/L}$ [$\ge 54 \text{ mg/dL}$]), level 2 (clinically significant; blood glucose <3.0 mmol/L [<54 mg/dL]), or level 3 (severe; no glucose threshold but requiring assistance from another person for recovery).

Outcomes

The primary objective of this trial was to compare the effect of CagriSema versus semaglutide on the change from baseline to week 32 in glycated haemoglobin. The secondary objectives compared the effect of CagriSema versus cagrilintide on the change from baseline to week 32 in glycated haemoglobin and the effect of CagriSema versus semaglutide and cagrilintide on other parameters of glycaemic control, bodyweight, safety and tolerability, and hypoglycaemia.

The primary endpoint was change in glycated haemoglobin from baseline to week 32 (used to assess both the primary and secondary objectives for glycated haemoglobin). Supportive secondary endpoints were change from

baseline to week 32 in bodyweight (% and kg), CGM-related endpoints,¹⁵ and change from baseline to week 32 in fasting plasma glucose (mmol/L). CGM endpoints included time in range (TIR) 3.9-10.0 mmol/L (70–180 mg/dL; % of readings) and time above range (TAR) >10.0 mmol/L (>180 mg/dL; % of readings) at week 32, and change from baseline to week 32 in mean glucose. Additionally, 24-hour CGM profiles were collected. Biomarkers including fasting glucagon, fasting serum insulin, high-sensitivity C-reactive protein (hsCRP), leptin, soluble leptin receptor, and a lipid panel were assessed. Post-hoc analyses evaluated the proportion of participants with glycated haemoglobin <7.0% or ≤6.5% or a reduction in bodyweight ≥10% or ≥15% at week 32, additional CGM endpoints of time in tight range (TITR) 3.9-7.8 mmol/L (70–140 mg/dL; % of readings) and time below range (TBR) <3.9 mmol/L (<70 mg/dL; % of readings) at week 32, and the leptin to soluble leptin receptor ratio. Safety assessments included adverse events, hypoglycaemic episodes, blood pressure, heart rate, and relevant laboratory assessments.

Statistical analysis

The sample size calculation aimed at quantifying the magnitude of expected variation in the estimated treatment difference (ETD) for the primary endpoint. Using an expected standard deviation of 1.0%, a planned sample size of 30 participants per treatment group (90 participants in total) would ensure, with 80% probability, that the 95% CI for the ETD would be within ± 0.56 percentage points of the mean. Efficacy analyses were performed in the full analysis population (all participants who had undergone randomisation), and safety analyses were assessed in the safety analysis population (all participants who had undergone randomisation and were exposed to at least one dose of the trial medication).

Treatment efficacy was evaluated using two estimands. The trial product estimand (primary estimand) evaluated the treatment effect for all randomised participants, assuming that all participants continued taking the trial product for the entire treatment duration and did not use rescue medication. The treatment-policy estimand (additional estimand) evaluated the treatment effect for all randomised participants, regardless of trial product discontinuation or use of rescue medication. Further information regarding the statistical analysis can be found in the appendix (p 4).

Role of the funding source

The sponsor of the study had a role in study design, monitoring, data collection, data analysis, and data interpretation. All authors had full access to all the data in the study, actively contributed to all drafts of the

manuscript, and made the decision to submit the manuscript for publication. Medical writing and editorial support

were funded by the trial sponsor.

Results

Between August 2, 2021 and October 18, 2021, a total of 162 participants were screened; 92 participants were randomly assigned to CagriSema (N=31), semaglutide (N=31), or cagrilintide (N=30). A high proportion of participants completed treatment ($87\cdot1\%$ with CagriSema, $90\cdot3\%$ with semaglutide, and 100% with cagrilintide) and completed the trial (94% with CagriSema and semaglutide, and 100% with cagrilintide). The trial product was discontinued by four ($12\cdot9\%$) participants treated with CagriSema, three ($9\cdot7\%$) participants treated with semaglutide, and no participants treated with cagrilintide (appendix p 15).

Baseline characteristics are presented in table 1 and in the appendix (p 6); 64% of participants were male, mean age was 58 years, and mean diabetes duration was 9 years. At baseline, mean glycated haemoglobin and bodyweight were 8.4% and 105.7 kg, respectively. Slight imbalances were observed for baseline glycated haemoglobin and diabetes duration between treatment groups. The representativeness of the trial population is described in the appendix (p 8).

A significantly greater reduction in glycated haemoglobin was observed from baseline to week 32 with CagriSema versus cagrilintide. Using the trial product estimand, mean change in glycated haemoglobin from baseline to week 32 was $-2 \cdot 2$ percentage points with CagriSema, $-1 \cdot 8$ percentage points with semaglutide, and $-0 \cdot 9$ percentage points with cagrilintide (figure 1). The ETD was $-0 \cdot 4$ percentage points (95% CI $-0 \cdot 8$ to $0 \cdot 0$; p= $0 \cdot 07$) for CagriSema versus semaglutide and $-1 \cdot 3$ percentage points (95% CI $-1 \cdot 7$ to $-0 \cdot 8$; p< $0 \cdot 001$) for CagriSema versus cagrilintide. Consistent results were observed using the treatment policy estimand (appendix p 16). A numerically greater proportion of participants reached the targets of glycated haemoglobin <7 $\cdot 0\%$ and $\leq 6 \cdot 5\%$ with CagriSema compared with semaglutide and cagrilintide (table 2).

A significantly greater reduction in bodyweight was observed from baseline to week 32 with CagriSema versus both semaglutide and cagrilintide. Using the trial product estimand, mean change in bodyweight from baseline to week 32 was -15.6% (-16.3 kg) with CagriSema, -5.1% (-5.3 kg) with semaglutide, and -8.1% (-8.4 kg) with cagrilintide (figure 1). The ETD was -10.5% (95% CI -14.1 to -7.0; p<0.001) for CagriSema versus semaglutide and -7.5% (95% CI -11.0 to -4.0; p<0.001) for CagriSema versus cagrilintide. Consistent results were observed using the treatment policy estimand (appendix p 16). A numerically greater proportion of participants reached the

target of $\geq 10\%$ and $\geq 15\%$ reduction in bodyweight with CagriSema compared with semaglutide and cagrilintide (table 2).

At week 32, TIR ($3\cdot9-10\cdot0$ mmol/L [70-180 mg/dL]) measured by CGM was 88.9% with CagriSema, 76.2% with semaglutide, and 71.7% with cagrilintide, and TAR was 10.3% with CagriSema, 23.7% with semaglutide, and 28.1% with cagrilintide (figure 2). Change from baseline in TIR and TITR were analysed post hoc, and were both significantly greater with CagriSema versus cagrilintide, but not versus semaglutide (appendix p 9). Twenty-four-hour CGM profiles at baseline and week 32 are presented in figure 2, and within-day glycaemic variability results are presented in the appendix (p 9). Significantly greater reductions in mean CGM-measured glucose from baseline to week 32 were observed with CagriSema versus both semaglutide (p=0.04) and cagrilintide (p=0.001; table 2). Fasting plasma glucose decreased from baseline to week 32 in all treatment groups; significantly greater reductions were observed with CagriSema versus cagrilintide (p=0.001), but not versus semaglutide (p=0.10; table 2).

Key observations for hsCRP, leptin, soluble leptin receptor, fasting serum insulin, C-peptide, proinsulin, and fasting glucagon from baseline to week 32 are summarised in the appendix (p 6). As a biomarker of interest, the ratio of leptin to soluble leptin receptor was investigated in a post-hoc analysis and showed a significantly differentiated effect from baseline at week 32 for CagriSema and cagrilintide compared with semaglutide (appendix p 10). Numerical reductions in certain lipids, including total cholesterol, triglycerides, low-density lipoprotein cholesterol, and very-low-density lipoprotein cholesterol, were present among all treatment groups appendix (p 6 and 17). Similar proportions of participants reported adverse events across treatment groups (table 3 and appendix p 11). Gastrointestinal adverse events occurred in 58%, 32%, and 33% of participants treated with CagriSema, semaglutide, and cagrilintide, respectively; all were mild or moderate in severity and the majority began during dose escalation (appendix p 18). A total of three participants reported injection-site reactions and no cases of acute gallbladder disease or acute pancreatitis were reported (appendix p 12). Two adverse events of retinal drusen and one adverse event of retinal haemorrhage were captured by a Medical Dictionary for Regulatory Activities (MedDRA) search, were mild in severity, and assessed as unlikely related to the trial products. No additional data were collected for these events as they were not considered events of diabetic retinopathy (appendix p 12). Two participants reported two serious adverse events with semaglutide and four participants reported five serious adverse events with cagrilintide (appendix p 13). No clinically significant or severe hypoglycaemic episodes (level 2 or 3) were reported. From baseline to week 32, the mean change in systolic blood pressure was -13 mmHg, 1 mmHg, and -3 mmHg with CagriSema, semaglutide, and cagrilintide, respectively, and mean change in pulse rate was 3

beats/min, 7 beats/min, and -1 beats/min, respectively (appendix p 19).

Discussion

In this exploratory trial, 32-week treatment with CagriSema resulted in a clinically relevant reduction in glycated haemoglobin of 2.2 percentage points versus 1.8 percentage points with semaglutide and 0.9 percentage points with cagrilintide. Furthermore, treatment with CagriSema resulted in significantly greater weight loss versus both semaglutide and cagrilintide.

Time in range was 89% at week 32 with CagriSema, a clinically relevant margin¹⁵ greater than the 76% and 72% achieved with semaglutide and cagrilintide, respectively, without increasing TBR, which remained low in all treatment groups. TITR at week 32 was 66%, 50%, and 37% for CagriSema, semaglutide, and cagrilintide, respectively. The numerically higher TIR and TITR observed at week 32 with CagriSema compared with semaglutide indicates a potential to further improve glycaemia versus semaglutide. Visual inspection of the 24-hour CGM profiles supported a flattening of the glucose curve from baseline to week 32 in all treatment groups, with the most pronounced improvements observed with CagriSema. Notable flattening was observed around expected mealtimes with CagriSema and cagrilintide, and to a lesser extent with semaglutide, where peaks were still visible, although mealtimes were not specifically recorded for any of the participants. These observations are consistent with the postprandial glucose-lowering effect observed with pramlintide, a short-acting amylin analogue approved as an adjunct to mealtime insulin treatment for type 1 and type 2 diabetes.¹⁶ Delayed gastric emptying, which has been previously observed with amylin agonist administration,¹⁷ may have also contributed to the visibly smaller mealtime peaks. The CGM results, alongside an observed decrease from baseline at week 32 in fasting serum insulin and C-peptide with CagriSema and cagrilintide, add to the efficacy of CagriSema¹⁸ and suggest mechanistic differentiation compared with semaglutide alone.

The significant reductions in bodyweight observed with CagriSema during this trial support previous findings of CagriSema and cagrilintide in people with overweight or obesity without type 2 diabetes.^{13,14} Weight loss of the magnitude observed with CagriSema, that had not plateaued at 32 weeks, has not been previously observed with pharmacological interventions in people with type 2 diabetes, a population who have historically underperformed in weight loss trials. Additionally, the weight loss observed with CagriSema (15.6%) was comparable to bodyweight loss observed in populations without type 2 diabetes,¹⁴ which is often not the case for pharmacological treatments including semaglutide.^{19,20} Weight loss of this magnitude can have disease-modifying effects in people with type 2

diabetes.⁵ Of note, the weight loss reduction observed with semaglutide $(-5 \cdot 1\%)$ was lower in this trial than previously reported (approximately -9% vs -3% with placebo at 32 weeks),²¹ potentially due to the small sample size, short duration, and absence of diet and exercise counselling, which was implemented in previous trials of subcutaneously administered semaglutide 2·4 mg in people with type 2 diabetes.²¹ Cagrilintide is expected to reduce bodyweight via similar mechanisms to native amylin, by interacting with the amylin and calcitonin receptors in the brain to control energy homeostasis.^{13,14,22}

While the glucose-lowering effect of semaglutide is well established,²⁰ this trial suggests that cagrilintide also has glucose-lowering properties. This glucose-lowering effect may be partly attributed to the robust weight loss,²³ but other effects of amylin agonist administration may have contributed, including slowing of gastric emptying, reduction in postprandial glucagon secretion, and synergistic effects with leptin that improve leptin responsiveness, insulin sensitivity, and reduce appetite.²⁴⁻²⁸ Of note, leptin responsiveness is thought to be reduced in people with obesity compared with those of a healthy weight.^{25,29} In this trial, differences were present in the ratio between circulating leptin and soluble leptin receptor with CagriSema and cagrilintide compared with semaglutide, suggesting a potential sensitising effect on leptin responsiveness.^{29,30} Indeed, leptin responsiveness has been associated with improvements in insulin sensitivity^{24,26}; however, further mechanistic studies are warranted to explore this association. It is of interest that clinically relevant improvements were observed in systolic blood pressure, lipid parameters, and hsCRP with CagriSema treatment after 32 weeks.

The safety profile of CagriSema was generally consistent with the glucagon-like peptide-1 receptor agonist and amylin analogue drug classes. Gastrointestinal adverse events were more common with CagriSema than with semaglutide or cagrilintide, however all were mild or moderate in severity and most had onset during dose escalation. Few serious adverse events were reported, and the proportion of participants completing treatment was high among all treatment groups, with only one discontinuation due to an adverse event in the semaglutide group. High on-treatment and in-trial retention was also notable among all treatment groups.

Strengths of this trial include the use of each individual component as a comparator to CagriSema and the use of CGM assessments for a comprehensive assessment of glycaemic parameters. Race and ethnicity demographics were largely representative of the US population in terms of the proportion of people who were of Black or African American race or of Hispanic ethnicity. Limitations of this trial include the small sample size, which has introduced

heterogeneity between treatment groups at baseline, including for sex, age, fasting plasma glucose, and glycated haemoglobin. Other limitations include the relatively short treatment duration.

Overall, in this phase 2 trial in people with type 2 diabetes, clinically relevant improvements in glycaemic control, including CGM profiles, were observed with CagriSema, as well as weight loss of a magnitude not previously reported with pharmacotherapies in this population. CagriSema also had an acceptable safety profile. These data support further investigation of CagriSema in this population in longer and larger phase 3 studies.

SDP acted as consultant, advisory board member, and/or speaker for Abbott, AstraZeneca, Bausch, Bayer, Boehringer Ingelheim, Dexcom, Eli Lilly, HLS, Janssen, Merck, Novo Nordisk, Pfizer, and Sanofi. They are/have been an investigator in clinical trials funded by AstraZeneca, Boehringer Ingelheim, Eli Lilly, Novo Nordisk, Pfizer, Prometic, and Sanofi. MD has acted as consultant, advisory board member, and speaker for Boehringer Ingelheim, Lilly, Novo Nordisk, and Sanofi; an advisory board member for Lexicon, Medtronic, Pfizer, and ShouTi Pharma Inc; and as a speaker for Amgen, AstraZenaca, Napp Pharmaceuticals, and Novartis. MD has received grants in support of investigator and investigator-initiated trials from AstraZeneca, Boehringer Ingelheim, Janssen, Lilly, Novo Nordisk, and Sanofi-Aventis.

Data sharing

Individual participant data will be shared in datasets in a deidentified, anonymised format. Shared data will include datasets from clinical research sponsored by Novo Nordisk completed after 2001 for product indications approved in both the EU and the USA. The study protocol and redacted clinical study report will be made available according to Novo Nordisk data sharing commitments. These data will be available permanently after research completion and approval of product and product use in both the EU and the USA (no end date). Data will be shared with bona fide researchers submitting a research proposal requesting access to data, for use as approved by the Independent Review Board (IRB) according to the IRB charter. These data can be accessed via an access request proposal form. The data will be made available on a specialised SAS data platform.

Acknowledgments

This trial was sponsored by Novo Nordisk A/S and is registered with ClinicalTrials.gov (NCT04982575). The authors thank the trial participants and the investigators and trial site staff who conducted the trial. Medical writing support was provided by Abbie Richold, BSc, of Apollo, OPEN Health Communications, and funded by Novo Nordisk, in accordance with Good Publication Practice (GPP) guidelines (<u>www.ismpp.org/gpp-2022</u>).

Data are for the full analysis population unless otherwise stated. Baseline information is defined as the latest planned assessment before dosing.

BMI=body-mass index. CagriSema=co-administered semaglutide and cagrilintide. DBP=diastolic blood pressure. eGFR=estimated glomerular filtration rate. FPG=fasting plasma glucose. N/A=not applicable. SBP=systolic blood pressure. SGLT2i=sodium-glucose cotransporter-2 inhibitor.

*BMI is calculated based on baseline measurements of bodyweight and height. [†]Observations are based on the safety analysis population. [‡]Baseline data for eGFR were collected during the 2-week screening period prior to initiation of treatment.

General disorders and administration-site conditions	5	16.1	8	40.4	0	0	0	0	5	16.7	27	128.8

Data are for the safety analysis population and from the on-treatment observation period.

ADA=American Diabetes Association. CagriSema=co-administered semaglutide and cagrilintide. E=events. GERD=gastroesophageal reflux disease. GI=gastrointestinal. R=event rate per 100 years of exposure time.

*One participant in the semaglutide group discontinued treatment due to an adverse event (diarrhoea). [†]Hypoglycaemic episodes were defined according to the ADA 2018 classification: level 1, blood glucose <3.9 mmol/L and ≥ 3.0 mmol/L; level 2, blood glucose <3.0 mmol/L; level 3, requiring assistance from another person for recovery. [‡]Five system organ classes in which adverse events were most frequently reported. All remaining adverse events by system organ class are included in the appendix (p 11). [§]GI adverse events are reported by preferred term for adverse events occurring in $\ge 10\%$ of participants among all treatment groups.

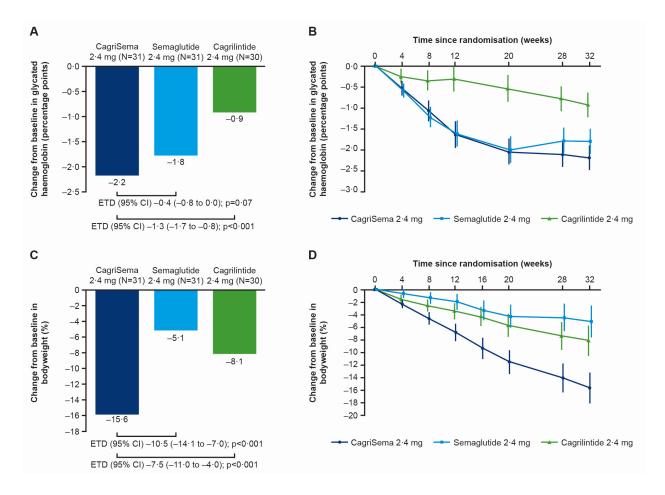

Figure 1: Change from baseline in glycated haemoglobin and bodyweight

Data are for the full analysis population and trial product estimand, and from the on-treatment observation period. The primary analysis for the trial product estimand was based on a mixed model for repeated measurements with baseline glycated haemoglobin as covariate, and treatment and sodium-glucose cotransporter-2 inhibitor (yes/no) as factors nested within the factor time using participants as random factor with unstructured within-participant covariance. Panels A and B show the mean change from baseline to week 32 and the mean change over time in glycated haemoglobin (percentage points), respectively. Panels C and D show the mean change from baseline to week 32 and the mean change over time in bodyweight (%), respectively. For panels A and C, n=27 in the CagriSema group, n=24 in the semaglutide group, and n=27 in the cagrilintide group.

Using the treatment policy estimand, mean change in glycated haemoglobin from baseline to week 32 was $-2 \cdot 1$ percentage points with CagriSema, $-1 \cdot 8$ percentage points with semaglutide, and $-0 \cdot 9$ percentage points with cagrilintide, and the ETD (95% CI) was -0.3 percentage points (-0.8 to 0.2; p=0.23) for CagriSema versus semaglutide and $-1 \cdot 2$ percentage points (-1.7 to -0.7; p<0.001) for CagriSema versus cagrilintide. Mean change in bodyweight from baseline to week 32 using the treatment policy estimand was $-14 \cdot 7\%$ (-15.3 kg) for CagriSema, -5.2% (-5.4 kg) for semaglutide, and -8.1% (-8.6 kg) for cagrilintide, and the ETD (p value) was -9.5% (-13.8 to -5.1; p<0.001) for CagriSema versus semaglutide, and -6.5% (-10.6 to -2.4; p=0.002) for CagriSema versus cagrilintide. Data for the treatment policy estimand are shown in the appendix (p 16).

CagriSema=co-administered semaglutide and cagrilintide. ETD=estimated treatment difference.

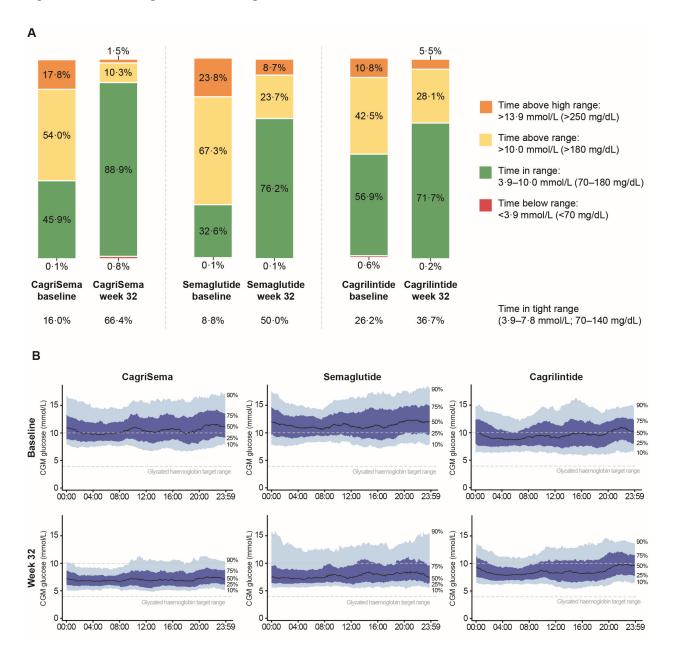

Figure 2: Continuous glucose monitoring observations

In panel A, data are for the full analysis population and from the on-treatment observation period. Panel A shows the time below range, time in range, time above range, and time above high range. For panel A, at baseline: n=31 in the CagriSema group, n=30 in the semaglutide group, and n=30 in the cagrilintide group; at week 32: n=26 in the CagriSema group, n=25 in the semaglutide group, and n=25 in the cagrilintide group.

In panel B, data are for the full analysis population and from the in-trial observation period. Panel B shows the 24hour CGM profiles; the black line signifies median; the blue bands signify the $10-90^{\text{th}}$ and $25-75^{\text{th}}$ centiles; and the grey lines signify the glycated haemoglobin target range of $3\cdot9-10\cdot0$ mmol/L; time since midnight is split into 5minute intervals.

CagriSema=co-administered semaglutide and cagrilintide. CGM=continuous glucose monitoring.
