ABSTRACT

We present observations of Swift J1112.2–8238, and identify it as a candidate relativistic tidal disruption flare. The outburst was first detected by *Swift*/Burst Alert Telescope (BAT) in 2011 June as an unknown, long-lived (order of days) gamma-ray transient source. We show that its position is consistent with the nucleus of a faint galaxy for which we establish a likely redshift of $z = 0.89$ based on a single emission line that we interpret as the blended [O II] $\lambda 3727$ doublet. At this redshift, the peak X-ray/gamma-ray luminosity exceeded 10^{47} erg s^{−1}, while a spatially coincident optical transient source had $i' \sim 22$ ($M_g \sim -21.4$ at $z = 0.89$) during early observations, ~ 20 d after the *Swift* trigger. These properties place Swift J1112.2–8238 in a very similar region of parameter space to the two previously identified members of this class, Swift J1644+57 and Swift J2058+0516. As with those events the high-energy emission shows evidence for variability over the first few days, while late-time observations, almost 3 yr post-outburst, demonstrate that it has now switched off. Swift J1112.2–8238 brings the total number of such events observed by *Swift* to three, interestingly all detected by *Swift* over a ~ 3 month period (< 3 per cent of its total lifetime as of 2015 March). While this suggests the possibility that further examples may be uncovered by detailed searches of the BAT archives, the lack of any prime candidates in the years since 2011 means these events are undoubtedly rare.

Key words: galaxies: nuclei – gamma-rays: galaxies.

1 INTRODUCTION

In recent years it has been assumed that the majority, if not all, large galaxies house at their cores a supermassive black hole (SMBH) ranging from many hundreds of thousands to billions of times the mass of our Sun (see the recent review by Graham 2015). These objects strongly influence, or are strongly influenced by, the properties of their hosts, as evidenced by certain galaxy-wide properties scaling with the masses of these SMBHs, such as in the M – σ relation (Ferrarese & Merritt 2000; Gebhardt et al. 2000). However, the cause of this link is not well understood. In order to better understand the SMBH demographic (particularly at the low-mass end where samples are of very limited size, see e.g. Reines, Greene & Geha 2013), and their co-evolution with their hosts, further examples must be studied in dwarf and distant galaxies.

However, in the case of a distant/dwarf galaxy lacking an active galactic nucleus (AGN), even confirming the existence of an SMBH can be difficult. Obtaining spatially resolved velocity disper-

sion measurements across the galaxy, looking for the gravitational influence of a massive central body, becomes impossible with current instrumentation when the angular size of the galaxy becomes too small. The detection and correct identification of a tidal disruption flare (TDF), however, unequivocally shows the existence of an SMBH within the flare’s host, irrespective of the host’s angular size or apparent magnitude.

A TDF is the luminous burst produced by the capture, disruption and subsequent accretion of a star on to a SMBH. They are typically characterized by a short-lived (months to years) transient with a high temperature ($> 10^4$ K) thermal spectral energy distribution (SED). They occur whenever a star passes within its tidal radius of the central SMBH ($r_t \sim R_*(M_{\text{BH}}/M_*)^{1/3}$) while remaining outside of the Schwarzschild radius (R_S ; Rees 1988), since crossing the latter would lead to the star being swallowed whole and thus produce no visible flare. Since $r_t \propto M_{\text{BH}}^{1/3}$ and $R_S \propto M_{\text{BH}}$, for a given radius (and mass) of star, there exists a maximum black hole mass for which the disruption will occur outside R_S (although in practice the spin of the black hole is also important; e.g. Kesden 2012a). Hence white dwarfs will only be disrupted by intermediate mass black holes ($\sim 10^5 M_\odot$), while main-sequence stars can produce

* E-mail: g.c.brown@warwick.ac.uk

flares with black holes up to $\sim 10^8 M_\odot$ and giants may be disrupted even around the most massive known black holes, though the likely accretion rates and time-scales are much longer than for more compact systems (MacLeod et al. 2013). Ultimately, observations of confirmed tidal flares may offer a new approach to measurements of black hole masses (Lodato & Rossi 2011; Gezari et al. 2012) and spins (Kesden 2012b).

A number of TDF candidates have been found in the UV (e.g. Gezari et al. 2008, 2009, 2012), soft X-rays (e.g. Brandt, Pounds & Fink 1995; Grupe et al. 1995; Bade, Komossa & Dahlem 1996; Cappelluti et al. 2009) and the optical (e.g. van Velzen et al. 2011; Cenko et al. 2012a; Arcavi et al. 2014). However, most of these were detected at low redshift, often less than $z = 0.1$ due to the necessity of multi-epoch photometry and astrometry, and the relatively shallow surveys from which they were selected. Probing these events to much greater distances, thus providing a way to characterize the SMBH mass distribution as a function of redshift, would require much more sensitive, high cadence surveys [such as the Large Synoptic Survey Telescope (LSST); Ivezić et al. 2014] or possibly chance gravitational lensing events (e.g. the $z = 3.3$ candidate; Stern et al. 2004). However, a new sub-class of these events, potentially observable out to much larger distances with current observing platforms, has provided us with a new way to observe these transients.

The first such event Swift J164449.3+573451 (henceforth Swift J1644+57), detected in 2011 March, exhibited extremely unusual high-energy behaviour. Detected initially as a gamma-ray burst (GRB) trigger with a long duration (~ 1000 s; Cummings et al. 2011a), the event remained bright and variable for several days, retriggering *Swift*/Burst Alert Telescope (BAT) on a further three occasions over the course of 48 h (Cummings et al. 2011b) making it clear this was not a standard GRB, short or long. X-ray monitoring with *Swift*/XRT showed a luminous flaring source that settled into a several-day long plateau before following an approximately power-law decay, all with considerable short-term variability superimposed upon it. The source was discovered to lie at a cosmological distance, coincident with the centre (< 150 pc to 1σ) of a faint star-forming host at a spectroscopically confirmed redshift of $z = 0.353$ (Levan et al. 2011), implying the isotropic X-ray luminosity of the event was $L_X = 10^{47} - 10^{48}$ erg s $^{-1}$ even at late times. In contrast, the coincident optical/infrared transient peaked at a more modest $L_{\text{opt/IR}} = 10^{42} - 10^{43}$ erg s $^{-1}$ even after correction for moderate internal extinction (Bloom et al. 2011).

Radio observations of Swift J1644+57 with the Expanded Very Large Array (EVLA) detected a rising unresolved source with an equipartition radius that implied a moderately relativistic expansion with Lorentz factor $\Gamma \sim 2$ and a formation epoch that coincided with the initial gamma-ray detection (Zauderer et al. 2011). The energetics measured by Zauderer et al. (2011), $\sim 3 \times 10^{50}$ erg at 22 d post burst, also corresponded to the Eddington luminosity for accretion on to a $10^6 M_\odot$ black hole. Müller & Gülltekin (2011) used a purely observational relation between X-ray luminosity, radio luminosity and the mass of black holes (ranging from high-mass Seyferts to stellar mass black holes) to estimate the mass of the SMBH that produced Swift J1644+57. The resulting weak constraint of $\log(M_{\text{BH}}/M_\odot) = 5.5 \pm 1.1$, was consistent with the black hole mass of $2 \times 10^6 - 10^7 M_\odot$ estimated by Levan et al. (2011) via the spheroid mass–black hole mass scaling relation of Bennert et al. (2011).

These unique broad-band properties marked Swift J1644+57 as a new class of transient. They suggested the detection of a flare situated in the nuclear region of a dwarf galaxy with energetics and

short-term variability consistent with an accretion event on to the central SMBH. But the lack of any previous activity in gamma-rays during the lifetime of Swift (Krimm & Barthelmy 2011), the spectroscopic classification of the galaxy as star forming (Levan et al. 2011) and the radio formation epoch (Zauderer et al. 2011) all indicated the accretion event was new and not part of any ongoing nuclear activity. Thus, the favoured explanation was taken to be that of the tidal disruption of a solar-type star that had also launched a moderately relativistic jet. However, this relativistic tidal disruption flare (rTDF) interpretation was not unchallenged, and other mechanisms, perhaps involving the tidal capture of a white dwarf (Krolik & Piran 2011) or massive star core collapse (Quataert & Kasen 2012; Woosley & Heger 2012), were postulated.

A second example, Swift J2058.4+0516 (Swift J2058+05; Cenko et al. 2012b), was detected in 2011 May. While apparently much fainter than Swift J1644+57, this was largely due to the much greater redshift ($z = 1.19$, cf. $z = 0.35$ for Swift J1644+57) and this was in fact a more luminous event. The bulk properties (peak luminosity, total energy, longevity, steep late-time cut-off) of the event matched well with those of Swift J1644+57 (Pasham et al. 2015) although there were several important differences. The X-ray light-curve decline was steeper (a power law with index ~ -2.2 , while Swift J1644+57 was remarkably near the theoretical $-5/3$ (Rees 1988; Phinney 1989), although recent numerical simulations suggest that accounting for stellar structure and closeness of approach, -2.2 is expected in half of all disruptions (Guillochon & Ramirez-Ruiz 2013) and the X-ray spectrum was somewhat harder (photon index ~ 1.6 , cf. ~ 2). In addition, the observed radio spectrum of Swift J2058+05 was very flat (ν^0) which contrasts strongly with the optically thick spectrum ($\nu^{1.3}$) of Swift J1644+57 (Pasham et al. 2015). Despite these differences, it was suggested that Swift J2058+0516 is the second member of the rTDF class, and in this case the observational differences may offer important diagnostics of the disruption process.

Another potentially related class of transient is that of the ultralong GRBs (ULGRBs; Levan et al. 2014). These events exhibit γ -ray emission lasting for thousands of seconds (one to two orders of magnitude less than the flares described above, but an order of magnitude longer than most GRBs). While multiple possible paths to their creation have been suggested (e.g. Campana et al. 2011; Thöne et al. 2011; Gendre et al. 2013), it is also possible that they are related to TDFs with a relativistic component, although in this case their shorter time-scales would imply a white dwarf disruption (Krolik & Piran 2011; Levan et al. 2014; MacLeod et al. 2014).

Relativistic TDFs are potentially observable out to much greater distances than their non-relativistic thermal TDF cousins due to their beamed emission, analogous to how GRBs have been shown to be detectable to extreme redshifts (e.g. GRB090423; Salvaterra et al. 2009; Tanvir et al. 2009). Levan et al. (2011) estimated that Swift J1644+57 would have been observable out to $z > 0.6$, while the redshift of Swift J2058+05 (Cenko et al. 2012b) ($z = 1.185$) shows certain members may be observable at even larger distances. Zauderer et al. (2011) suggest that the radio component would be detectable out to $z \sim 6$, potentially making large-scale radio surveys a powerful method for the detection of these events.

Such rTDFs also evolve on very short time-scales compared to AGN and so offer a way to study jetted accretion events across their whole lifetimes on human time-scales, evidenced by observations of Swift J1644+57 showing that the jet has now apparently shut-off (Zauderer et al. 2013). This is a virtual impossibility in the vastly longer lived AGN duty cycles which may last in excess of 10^7 yr

(e.g. Hopkins & Hernquist 2009). In addition, the relativistic jets emitted by these events have been suggested as a possible source of ultrahigh energy cosmic rays (e.g. Farrar & Gruzinov 2009; Bloom et al. 2011; Wang et al. 2011; Farrar & Piran 2014).

Given the potential importance of studying these events, it is concerning that it is unclear whether Swift J2058+05 would have attracted such detailed follow-up in the absence of Swift J1644+57, considering to its less immediately impressive nature. In addition, the notable temporal coincidence of the two bursts, being only two months apart in the then ~ 7 yr that *Swift* had been operating, led to the suggestion at the time that further examples within the *Swift* archive may have been overlooked (e.g. Levan et al. 2011).

Here, we present observations of Swift J1112.2–8238 (henceforth Swift J1112–8238) which was detected by the *Swift* BAT in 2011 June and whose nature has to date been uncertain. Our spectroscopic observations establish a cosmological redshift for the transient, and we demonstrate optical variability close to the nucleus of a faint galaxy. We analyse the inferred physical properties, comparing them to the properties of previous *Swift* flare classifications including the recently discovered ULGRBs, and to the established relativistic TDF candidates, leading us to suggest that Swift J1112–8238 is also a candidate rTDF.

All magnitudes presented in this paper are in the AB magnitude system. Where necessary, we use a standard Λ cold dark matter cosmology with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.3$ and $\Omega_\Lambda = 0.7$.

2 OBSERVATIONS

2.1 *Swift* BAT data

The outburst of Swift J1112–8238 was originally discovered by the *Swift* telescope (Gehrels et al. 2004) in a four day integration by the BAT (Barthelmy et al. 2005) between 2011 June 16 and 19 (MJD 55728–55731; Krimm et al. 2011). We choose to set the trigger time to 2011 June 16 UT 00:01, although in practice a precise trigger time is poorly defined. The count rate in gamma-rays across this period was $(2.9 \pm 0.7) \times 10^{-3} \text{ ph s}^{-1} \text{ cm}^{-2}$ with a peak daily average rate of $(1.9 \pm 0.5) \times 10^{-2} \text{ ph s}^{-1} \text{ cm}^{-2}$ recorded on the 16th (Krimm et al. 2011). This peak, though high, was not in itself sufficient to trigger the automated transient monitor which has a 5σ burst detection threshold (Krimm et al. 2011, 2013). We utilize the available BAT daily average light curves¹ extending back as far as the launch of *Swift* in 2005 and confirm that there was no pre-trigger or post-burst activity above a 5σ threshold level at the flare’s position over any four-day window. We also note that Krimm et al. (2013) report no evidence for additional flares from the source. The light curve (gamma-ray, X-ray, optical) is shown in Fig. 1.

2.2 X-ray data

Initial X-ray data was obtained by the *Swift* X-Ray Telescope (XRT; Burrows et al. 2005) in a 3000 s target of opportunity observation approximately 10 d after the initial trigger (MJD 55741.7; Krimm et al. 2011). The source was well detected with an observed flux of $1.4_{-0.1}^{+0.1} \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2}$. An X-ray monitoring programme continued for a further 30 d with all observations obtained in photon

Figure 1. (Left) A GMOS-S i' band finding chart for Swift J1112–8238. (Right) A comparison between the source at ~ 20 d (Top) and at ~ 1.5 yr (Bottom) post trigger, each panel 15 arcsec across. The extended host’s structure is far clearer in the later epoch, due in part to both the decline of the optical transient and the greatly improved seeing.

counting (PC) mode. We obtained reduced XRT products from the *Swift* archive,² created using the techniques outlined in Evans et al. (2007, 2009, 2010). The enhanced X-ray position derived from the UV/Optical Telescope (UVOT) boresight correction is RA = 11:11:47.32 Dec. = $-82:38:44.2$ (J2000) with a 90 per cent error radius of 1.4 arcsec. The combined spectrum of all available PC-mode data is well fitted by an absorbed power law of photon index $\Gamma_{\text{ph}} = 1.33 \pm 0.08$ and $N_{\text{H}}(\text{int}) = 2.4_{-1.6}^{+1.8} \times 10^{21} \text{ cm}^{-2}$ consistent with the Galactic value of $1.8 \times 10^{21} \text{ cm}^{-2}$ (Willingale et al. 2013). Although the number of counts is small, there is no evidence for spectral evolution through the observations.

The light curve over the same period exhibits a gradual decay but with marked variability (a factor of ~ 2 in flux) between individual snapshots (uninterrupted pointings). We obtained further late-time observations in 2014 April, with a total XRT exposure time of 6960.3 s (in PC mode). This observation provides an upper limit on the source flux of $F_X < 4 \times 10^{-14} \text{ erg s}^{-1} \text{ cm}^{-2}$ (99 per cent, determined via the Bayesian method of Kraft, Burrows & Nousek 1991). This is a factor of ~ 250 fainter than the peak luminosity confirming the source’s transient nature.

2.3 Optical imaging

Following a UVOT non-detection ($b > 22.0$ mag; Krimm et al. 2011) made at the beginning of the X-ray monitoring programme, we obtained observations in the i' band with the Gemini Multiple Object Spectrograph on Gemini South (GMOS-S; Hook et al. 2004) at 2011 July 3 UT 00:58, 17 d after initial trigger (Berger & Chornock 2011). We performed later follow-up with GMOS-S in the r' and i' bands at 1.5 yr post-trigger (starting 2012 December 13 UT 06:50), and with the FOcal Reducer and low dispersion Spectrograph 2 (FOR2) on the Very Large Telescope (VLT) at 2 yr post-trigger (starting 2013 August 31 UT 23:31) in I and z' . In addition, as part of the GMOS-S spectroscopic follow-up, a number of short exposure acquisition images were taken in r' (starting at 2012 December 16 UT 07:30 and 2012 December 23 UT 05:16) and in i' (starting at 2014 January 3 UT 07:01, ~ 3 yr post trigger). All of this imaging was reduced using standard IRAF and ESOREX data

Table 1. Swift J1112–8238 optical photometry. Limits are stated to 3σ . Photometry is presented without host subtraction, although it is likely that the late epochs represent the host; that is, not significantly contaminated by transient light. Note the i' GMOS-S magnitudes were calculated using relative photometry from the VLT I -band image and so have a minor systematic uncertainty not included here. All observation times are measured from the beginning of the first day of the 4 d *Swift* trigger observation (2011 June 16 UT 00:01). The seeing of each observation is included as it affects the contamination from the nearby bright star.

MJD	ΔT (d)	Instrument	Filter	Magnitude	Seeing (arcsec)
55745.1	17.1	GMOS-S	i'	22.10 ± 0.10	1.4
55749.0	21.0	GMOS-S	i'	21.96 ± 0.10	1.4
56274.3	546.3	GMOS-S	r'	23.74 ± 0.17	0.7
56274.3	546.3	GMOS-S	i'	22.76 ± 0.12	0.7
56277.3	549.3	GMOS-S	r'	23.60 ± 0.26	0.8
56284.2	556.2	GMOS-S	r'	>22.84	0.9
56536.0	808.0	FORS2	z'	>22.10	1.6
56538.0	810.0	FORS2	I	23.28 ± 0.25	1.5
56538.0	810.0	FORS2	z'	23.29 ± 0.29	1.4
56660.3	932.3	GMOS-S	i'	>22.37	1.4

reduction techniques. We note that the presence of a nearby bright star ($R = 15.8$ mag at an angular distance of ~ 5 arcsec, Fig. 1) complicated the analysis of this source. We remove the majority of the flux from this contaminating star by subtracting a model stellar PSF, constructed as a median-averaged radial light profile for the star in question. We also considered models for the PSF from stars elsewhere in the image, subtracting a rotated copy of the contaminating star, or modelling the star directly via Moffat or multiple Gaussian fits. All these methods were hampered by the existence of other objects close to the star, or left clear residuals in the data.

Photometric calibrations for the i'/I band was completed through comparison with observations of photometric standards analysed via the ESOREX FORS2 pipeline, the expected systematic offset between the GMOS i' and FORS2 I filters having been deemed negligible in this low signal to noise regime. The non-standard filter z' was instead calibrated through comparison with the FORS2 standard star, Feige 110, which was observed within a few nights of our observations. Finally, the r' band was calibrated with reference to the Gemini standard zeropoints.³

The resultant photometry is detailed in Table 1 and plotted in Fig. 2. The early time observations showed a point-like source while later observations (>1 yr) reveal emission with a flux a factor ~ 2 lower than recorded at early times. Modelled photometry of the late-time emission with a Sérsic profile using GALFIT (Peng et al. 2002, 2010) was consistent with the aperture photometry detailed above, while PSF-matched point-source photometry (completed by scaling a PSF built from the image) yields results a magnitude dimmer, indicating the late-time source is extended.

The photometry has been corrected for Galactic extinction, with $E(B - V) = 0.253 \pm 0.009$, based on values derived from Schlafly & Finkbeiner (2011) and accessed via the NASA/IPAC Infrared

Science Archive.⁴ The individual bandpass corrections were approximated from the corresponding Sloan Digital Sky Survey filter corrections and thus have a minor systematic uncertainty not included in Table 1.

2.4 Spectroscopy

Optical longslit spectroscopy of Swift J1112.2–8238 was obtained on GMOS-S on 2012 December 16 and 23 using the R400_G5325 grating and independently on FORS2 using the 300I+11 grism on 2013 September 5. The GMOS-S spectra had a combined integration time of 2400 s (4×600) with spectral resolution of ~ 7 Å and a spectral range of 3870–8170 Å. The FORS2 spectrum also had an integration time of 2400 s (4×600) with spectral resolution of ~ 12 Å and a spectral range of 5100–11 000 Å. The standard recommended Gemini IRAF and FORS2 ESOREX data reduction was carried out on the appropriate spectra.

In all spectra, a single, weak emission feature was observed at ~ 7045 Å (Fig. 3), with a significance of $\sim 10\sigma$ in the GMOS spectrum. No continuum flux, or additional emission lines were seen. The line does not lie at the position of any common zero redshift features. It is offset by ~ 600 km s $^{-1}$ from the He 7060 Å line that is sometimes seen in accreting binaries (Marsh, Horne & Rosen 1991). However, in these binaries the line is broad, and many other emission features are seen. In addition, the existence of an underlying extended source, interpreted as the host of the transient, greatly reduces the probability of a Galactic origin as nebulae are the only Galactic source likely to be resolvable, and these typically show multiple emission lines. This indicates that Swift J1112–8238 is not a Galactic source.

The non-detection of other lines proximate in wavelength disfavors the identification of this line as either [O III]($\lambda\lambda 4959, 5007$ Å) or H β at $z \sim 0.4$, since in either case we would expect to observe the other lines. If the line were H α at $z = 0.07$, we may expect to observe either [N II] $\lambda 6584$, or H β and [O III], since all lie within the spectral window covered by our GMOS observations. The expected H β flux can be calculated directly (under the assumption the observed line is H α , and that the host galaxy extinction is minimal, as implied by the X-ray absorption). However, the combination of grating efficiency and Galactic reddening mean that we do not expect to observe H β in our observations at $>1.5\sigma$. The [O III] lines can frequently be substantially brighter than H β , and for a galaxy of metallicity $12 + \log(\text{O}/\text{H}) \sim 7.8$, consistent with the inferred absolute magnitude at $z = 0.07$ (rest frame $M_r \sim -14.8$; Sweet et al. 2014), we would expect [O III] ($\lambda 5007$ Å) to be a factor ~ 6 brighter than H β . Accounting for foreground extinction and grating efficiency as before, we estimate we would expect to observe it at $\sim 8\sigma$, whereas no line is present at this location. Any emission at the location of [N II] $\lambda 6584$ would be well below the detection limit given this assumed metallicity. We also note that at $z = 0.07$ the absolute magnitude of the galaxy of $M_i > -15$ would be unusually faint. Given these combined constraints we disfavor the origin of the line as H α .

Hence we identify the line as O II ($\lambda 3727$ Å) at a redshift $z = 0.8901 \pm 0.0001$. In this case, the redward emission lines are beyond the range of our GMOS spectroscopy, and lie in bright sky lines in our FORS observations, precluding their detection. The low resolution of the spectra means that we are unable to resolve the doublet in this case. This interpretation is supported by the observed

Figure 2. The light curves for Swift J1112–8238 in various wavebands from a few hours to ~ 1000 d post-trigger. The time axis is displayed in both seconds and days in the observer frame. In all panels, the right-hand axis indicates an isotropic equivalent luminosity or equivalent optical absolute magnitude. (Top) The median subtracted *Swift*/BAT daily average light curve in the 15–150 keV range, cut at 10^7 s post trigger for clarity. Note that the vertical scale is linear, and there are no significant detections beyond the first few days. (Middle) The *Swift*/XRT light curve in the 0.2–10 keV range. The green line indicates a $t^{-1.1}$ fit on the data preceding the sharp decline at ~ 30 d post trigger. In addition, the X-ray luminosities for Swift J1644+57 and Swift J2058+05 have been plotted. To allow for a direct comparison between the light curves, Swift J1644+57’s and Swift J2058+05’s light curves have had a cosmological time dilation correction to place them as though they had occurred at the same redshift as Swift J1112–82. (Bottom) The optical light curves from GMOS-S and FORS2 photometry. There is considerable optical variability between the early and late-time i'/I -band magnitudes and the late-time (> 1.5 yr) magnitudes are assumed to be at host level.

Figure 3. The (top) GMOS and (bottom) FORS2 spectra showing the clear emission line at a wavelength of ~ 7045 Å, interpreted as the O II emission line, though the low resolution and line signal to noise preclude the possibility of resolving its doublet nature. The position of the removed sky lines are indicated as dashes between the two spectra. The scale is in units of Angstroms.

galaxy colours. After correction for foreground extinction they are relatively red in $r - i \sim 0.9 \pm 0.2$, and bluer $i - z \sim -0.5 \pm 0.3$ (based on the ~ 550 d Gemini i' -band photometry). Although the errors are large, this is consistent with the presence of a Balmer break between the r - and i -bands, as might be expected for $z = 0.89$.

3 DISCUSSION

Our spectroscopic observations have confirmed the existence of a single emission line that is inconsistent with any zero redshift lines and consistent with our adopted redshift, $z = 0.8901 \pm 0.0001$.

In this section, we provide a short summary of the inferred rest-frame transient and host properties and then compare them to the properties of possible progenitors.

3.1 Physical properties

At the time of the first X-ray observations (10 d post trigger), the isotropic X-ray luminosity of the source was $\sim 6 \times 10^{46}$ erg s $^{-1}$. The source showed an approximate power-law decay with time of $t^{-1.1}$. However, this had considerable short-time-scale variability superimposed upon it, with factor of 2 differences in flux on

Figure 4. A zoomed in region (~ 5 arcsec, North up, East left) around Swift J1112–8238, ~ 550 d after initial detection, smoothed via a 3 pixel Gaussian convolution for clarity. The positions of the optical transient centroid, as measured 17 (left) and 21 (right) days after trigger with the IRAF command IMEXAM, are displayed as red 1σ error circles. Similarly, the host optical centroid (white) as measured via a Sérsic profile fit with GALFIT is plotted as a white 1σ error circle. This error is a lower limit based on the assumption of a Gaussian profile with FWHM equal to twice the half-light radius of the Sérsic fit. The transient positions are thus coincident with the central position to 1σ and 2σ , respectively. The consistency of these positions makes an association of the event with the SMBH in the galaxy plausible. It should be noted, though, that due to the low surface brightness and possible complex morphology of the host galaxy the host centroid is subject to substantial systematic uncertainty.

time-scales of a few thousand seconds ($>10^6$ s after the initial outburst). The X-ray spectrum was well fitted by a power-law spectrum with $\Gamma = 1.33$ and there was no evidence of spectral evolution. While multicomponent fits to the time series data involving a broken power law or a flare produce statistically better fits, this may simply be due to the intrinsic short-term variability of the source and the sparse sampling of the X-ray light curve, precluding the inference of more detailed information about the source.

By assuming the late-time optical epochs represent host level flux that is uncontaminated by transient light, we can subtract this from our earlier observations. This was done through the use of the image subtraction software ISIS (Alard & Lupton 1998). We aligned, convolved and subtracted the late-time (~ 1.5 yr) image from the early time (17 and 21 d) images in i' . The subtractions left a clear, point source residual in each image with an inferred position that lay at $0.11 \text{ arcsec} \pm 0.12 \text{ arcsec}$ and $0.22 \text{ arcsec} \pm 0.11 \text{ arcsec}$ (1σ) from the centroid of the host galaxy, determined using a Sérsic profile fit to the late-time image using the GALFIT software package, as shown in Fig. 4. The error on the host centroid position is determined under the assumption of a Gaussian profile with full width at half-maximum (FWHM) equal to the half light radius from the GALFIT Sérsic fit. The apparent asymmetry of the host means that this represents a lower limit on the true error in the centroid position. At the inferred redshift, our tightest constraint places the transient 0.85 ± 0.93 kpc from the centre of its host, for which the half light radius is ~ 6 kpc.

The host subtraction also allows us to isolate the optical transient light, determining an absolute magnitude of $M_{i'} = -21.4$, equat-

ing to a luminosity of $\sim 1 \times 10^{43} \text{ erg s}^{-1}$. The underlying host has a comparable absolute magnitude, $M_{i'} = -21.7$ (rest frame M_g at $z = 0.89$). Based on the luminosity function of galaxies from Gabasch et al. (2004) this places it near L^* at $z = 1$ (at a redshift of 0.89, the i' band equates roughly to rest frame g' band for which, in the redshift range 0.85–1.31, the L^* magnitude is -21.7).

3.2 Comparison to other sources

3.2.1 GRBs

Swift detected GRBs, are typically detected on time-scales much shorter than those for Swift J1112–8238. The majority arise from standard rate triggers, although a significant minority are longer lived and trigger the detector via image triggers, sometimes on time-scales of >1000 s. However, even the ULGRBs (Levan et al. 2014) that have durations of $\sim 10^4$ s are much shorter than Swift J1112–8238, whose several-day long γ -ray emission would imply a duration (if defined as T_{90} as for GRBs) of closer to 10^6 s. Hence on the basis of the gamma-ray properties alone, Swift J1112–8238 is a much closer analogue with Swift J1644+57 and Swift J2058+0516 than with any identified population of GRBs.

The X-ray properties are also apparently distinct, since the inferred isotropic X-ray luminosity lies an order of magnitude above GRBs at a similar epoch (see e.g. Nousek et al. 2006; Levan et al. 2014), and GRB afterglows at such late times seldom show such pronounced variability (likely due to the lack of engine activity). Despite the longevity of the gamma-ray emission in ULGRBs, their late-time afterglows are generally consistent with, if not slightly fainter than (Campana et al. 2011; Thöne et al. 2011; Evans et al. 2014), those of normal long GRBs (IGRBs), and so the X-ray properties also would suggest a physically distinct system.

The optical properties of Swift J1112–8238 are rather less conclusive. The optical transient luminosity is comparable with the brightest end of the GRB afterglow distribution (e.g. Kann et al. 2011), although given the X-ray brightness the inferred X-ray to optical spectral slope is very flat ($\beta_{\text{OX}} \sim 0.14$). If the emission mechanisms were similar to GRBs this would identify the counterpart of Swift J1112–8238 as a dark burst, and would imply significant extinction (Fynbo et al. 2009; Perley et al. 2013), the correction for which would make the afterglow the brightest seen. Alternatively, one may ascribe rather different emission mechanisms to the counterpart to Swift J1112–8238, in which case little extinction may be needed. It is interesting to note in this regard that Swift J2058+0516 also has a very flat $\beta_{\text{OX}} \sim 0.11$, despite a strong UV-SED that implied little extinction (Cenko et al. 2012b; Pasham et al. 2015).

Finally, one can also contrast the locations of Swift J1112–8238 with those of GRBs. LGRBs tend to trace the brightest regions of their host (Fruchter et al. 2006) which, given the low spatial resolution of the optical images and small angular size of the galaxy, might show itself as a coincidence of the transient position and the host centroid. Indeed, in the study of Fruchter et al. (2006) approximately 1/6 of the bursts were consistent with the brightest pixels in their host galaxies at HST resolution. Since we currently lack such high-resolution images the strength of the association of Swift J1112–8238 with its host nucleus is rather weaker than in the cases of Swift J1644+57 and Swift J2058+0516. However, in the majority of other regards its properties find a much better match with these events than either with normal IGRBs, or the ULGRB population.

Figure 5. The X-ray luminosity and optical absolute magnitude plotted for a number of extragalactic transients, including AGN flares and GRBs at late times. Swift J1112–8238 is more X-ray luminous at $\sim 10^6$ s than GRBs at similar epochs and, while the brightest X-ray blazar flares can match it, Swift J1112–8238 is very optically underluminous in comparison. It instead occupies a region of the parameter space devoid of other sources except Swift J1644+57 and Swift J2058+05. At early times the luminosity of these flares exceeds 10^{48} erg s $^{-1}$, and is in excess of 10^{46} erg s $^{-1}$ at 10^6 s. This is more luminous than ‘classical’ TDFs, which exhibit markedly lower X-ray luminosity (10^{44} erg s $^{-1}$), although none of these have been observed close to peak. Adapted from Levan et al. (2011).

3.2.2 AGN

The apparent coincidence of the transient position and the host centroid makes an association with the central SMBH of the galaxy plausible, and therefore possibly with ongoing AGN activity. No catalogued source is consistent with the position of Swift J1112–8238 in either the SUMSS 843GHz survey (60 per cent complete down to 6 mJy, 100 per cent to 8 mJy; Bock, Large & Sadler 1999; Mauch et al. 2003) or the AT20G 20GHz survey (91 per cent complete to 100 mJy; Murphy et al. 2010). This places limits on the pre-flare underlying radio emission of the host to the 10^{25} – 10^{26} W Hz $^{-1}$ level, which is only capable of ruling out the most luminous BL Lac type objects (Marchã & Caccianiga 2013). However, while the X-ray luminosity of the brightest blazar flares can reach the levels observed in Swift J1112–8238, this is generally accompanied by optical emission many magnitudes brighter than presented here, as seen in Fig. 5. In addition, our late-time X-ray limit places constraints on any underlying activity to a limit of $L_X < 10^{44}$ erg s $^{-1}$, fainter than the majority of quasars. For these reasons, we disfavour the identification of this flare as a blazar flare.

3.2.3 Relativistic tidal disruption flares

The association of the optical flare with the inferred location of the SMBH may indicate the discovery of a new tidal disruption flare. In order to determine if this is plausible, we estimate the mass of the black hole expected to occur within a galaxy of this size. Kauffmann et al. (2003) measure mass to light ratios of galaxies for a given redshift and rest-frame $g - r$ colour. At a redshift of 0.89, this equates roughly to a $i - z$ band colour in the observer frame. Based on an $i - z$ colour of -0.5 the mass to light ratio is ~ 0.1 , and, coupled with the rest-frame g -band (observer frame i -band) absolute magnitude of -21.7 , implies a relatively high galaxy mass

of $2 \times 10^9 M_\odot$. The stellar mass to black hole mass scaling relation of Bennert et al. (2011), produces a lower estimate for the SMBH mass of $\sim 5 \times 10^6 M_\odot$ (although there is considerable scatter in this relation and it is unclear whether the relation is applicable to such low masses) which is approximately consistent with the result obtained using the method from Häring & Rix (2004) of $\sim 2 \times 10^6$ (by assuming that the stellar mass estimate represents an upper limit on the bulge mass of the host). Both of these latter estimates are well within the $10^8 M_\odot$ limit for a Sun-like star to be disrupted by a SMBH and produce a visible TDF, making a TDF origin plausible.

From Fig. 5, we note that the optical absolute magnitude and X-ray luminosity of Swift J1112–8238 places it in a region of phase space that is devoid of any sources with the exception of the aforementioned relativistic TDF candidates Swift J1644+57 and Swift J2058+05. These candidates also match well with this new flare in their late-time X-ray light curves as shown in Fig. 2, particularly in the case of Swift J1644+57. The overall power-law decay observed over the 30 d of *Swift*-XRT follow-up of Swift J1112–82 is somewhat shallower than that of the other candidates with an index of ~ -1.1 . Swift J2058+05 had a much steeper decay at a similar epoch with an index of ~ -2.2 , while Swift J1644+57 had a late-time decay remarkably close to the $t^{-5/3}$ relation suggested to be a feature of TDF light curves (Rees 1988; Phinney 1989).

However, this decay index is somewhat sensitive to the choice of T_0 , which in this case is poorly defined, due in part to the unusual trigger method. Further, while often T_0 is taken to be the time at which the flare becomes observable, the true T_0 occurs some time earlier at the point of return of the most bound material which may precede emission by several days. In order to be consistent with a $t^{-5/3}$ decay, the ‘true’ T_0 would have to have been 12_{-4}^{+6} before the start of the *Swift* detection image. This may not be unreasonable, since Swift J1644+57 was active at least 4 d prior to its first GRB trigger, and had a 3σ detection on a single day, 14 d earlier

(Krimm & Barthelmy 2011). Constraints on T_0 have been attempted in detailed models of previous flares (e.g. Guillochon, Manukian & Ramirez-Ruiz 2014), however the lack of comprehensive follow-up precludes that possibility in this case. Perhaps even more importantly, the short duration over which observations were made also makes it difficult to determine the behaviour of the light curve within the context of the longer term emission. Indeed, Swift J1644+57's light curve was relatively flat at a similar epoch. Calculations considering more detailed transport of material through the disc point to a more complex picture, in which the $t^{-5/3}$ decline is only present in certain bands and over a rather restricted range of time (Lodato & Rossi 2011), while even more recent calculations suggest that the $t^{-2.2}$ decay seen in Swift J2058+0516 should be present in half of disruptions (Guillochon & Ramirez-Ruiz 2013). These predictions show that the X-ray flux can plateau over a period of tens of days after the initial disruption meaning the shallow decay of Swift J1112–8238 cannot place strong constraints on its nature. However, it should be noted that these simulations concern the disc emission, whereas, in relativistic TDFs, the X-ray emission is thought to be dominated by the jet. It is unclear if the assumption of a direct correlation between the jet and disc emission is reasonable.

Spectrally, the low number of counts recorded in Swift J1112.2–8238 restricts the information that can be extracted. However, the spectrum is well fitted with a single, absorbed power law with a relatively hard spectral index $\Gamma = 1.33 \pm 0.08$, (w-stat/dof = 574/586). This is somewhat harder than the late-time power-law index in Swift J1644+57 ($\Gamma \sim 2$) or in Swift J2058+0516 ($\Gamma \sim 1.6$). One area in which previous rTDFs differ is in the apparent correlation between hardness and flux. Swift J1644+57 exhibits spectral softening as it fades (Levan et al. 2011), while Swift J2058+0516 appears to harden (Cenko et al. 2012b). For Swift J1112.2–8238 it is not possible to discern any variation in spectrum with flux level.

The rapid variability observed in the X-ray emission can place constraints on the nature of the emission region. While the variability is not as dramatic as that observed in Swift J1644+57, where factor of 100 changes in flux were observed on time-scales of ~ 100 s, there is still evidence for factor of 2 variability on time-scales of a few thousand seconds. Unfortunately, the brightness of the source precludes timing at much higher resolution, and so light-travel time arguments would only place weak constraints on the size of the emitting region ($< 10^{15}$ cm, or $100 R_s$ for a $\sim 10^7 M_\odot$ black hole). More compellingly, the gamma-ray emission at the time of the first XRT observations is close to the Eddington luminosity of a $10^9 M_\odot$ black hole, and an extrapolation to early times suggests it was brighter still. The expected black hole mass is a factor of several hundred small than this, it is unlikely that a black hole could accrete at such high super-Eddington rates, so while the constraints on beaming are weaker than for Swift J1644+57 we still believe this is the most likely explanation for Swift J1112–8238.

The lack of more comprehensive optical follow-up precludes the building of an optical SED which would help distinguish between the thermal SEDs of previous TDFs, (e.g. ASASSN-14ae, Holoien et al. 2014; PS1-10jh, Gezari et al. 2012), for which the peak absolute magnitudes are loosely consistent, and the differing, non-thermal emission mechanisms suggested in Burrows et al. (2011) and Bloom et al. (2011) for rTDF candidates. One of these models involves a blazar-analogue combination of inverse Compton emission at high frequencies (X-ray/ γ -ray) with a second peak at low frequencies (Optical etc.) from synchrotron emission. Alternatively the emission in different wavebands may come from spatially separate emission regions. In the light curves of Swift J1644+57,

limits on optical/radio short-term variability set the emission apart from the rapidly varying high-energy emission. Under the assumption of a spherical emitting region with a blackbody temperature of 10^5 K (10^4 K), the radius of the region emitting optical light in Swift J1112.2–8238 would be about $\sim 3 \times 10^{15}$ cm ($\sim 1 \times 10^{16}$ cm). This is approximately consistent with 3 (10) times the tidal radius of a of Sun-like star around a $10^7 M_\odot$ black hole. This result is similar to those obtained from analysis of optical TDFs, perhaps unsurprisingly as the optical luminosity of Swift J1112–82 is only a factor of a few higher than seen in some other TDFs (e.g. van Velzen et al. 2011; Gezari et al. 2012). This may suggest a common mechanism for the optical emission from both relativistic and thermal TDFs.

It is also interesting to note Swift J1112–8238 shows a sharp decline in its X-ray flux at ~ 40 d post trigger. This may be indicative of dipping as seen in Swift J1644+57 (Bloom et al. 2011; Levan et al. 2011; Saxton et al. 2012) at similar times, or perhaps of a longer term cessation of activity as identified in Swift J1644+57 at much later epochs of ~ 1.5 yr (Berger et al. 2012; Levan & Tanvir 2012; Sbarufatti et al. 2012) and similarly in Swift J2058+05 (Pasham et al. 2015). In any case, the final epoch of observations results in a limit which is significantly below the extrapolation of the early emission, requiring either a steepening of the decay or a rapid drop. This suggests broad similarities between the different events, although the sparse sampling of Swift J1112–8238, makes it difficult to rule out alternate interpretations.

With the previous rTDF candidates, a variable radio source with a measured Lorentz factor of ~ 2 or higher was detected (Zauderer et al. 2011; Cenko et al. 2012b). In addition the inferred formation epoch from Swift J1644+57 implied a recently formed source, consistent with the start of the higher energy emission. This helped lead to the suggestion of a newly formed relativistic jet that accompanied the TDF. The lack of post-flare radio data precludes a similar analysis in the case of Swift J1112–8238. However, a Swift J1644+57-like radio light curve would be observable even several years after the flare and thus radio constraints may yet be obtainable.

4 IMPLICATIONS

If Swift J1112–8238 is indeed a member of the same class of object as Swift J1644+57 and Swift J2058+0516 then it brings the total number of such events, as selected by the high-energy emission, to three. Radio observations of thermal (non-relativistic) TDF candidates (e.g. Bower 2011; Bower et al. 2013; van Velzen et al. 2013) have been used to attempt to determine the number of ‘off-axis’ members and in the case of Bower et al. (2013), a few candidates may have been discovered. However, it is clear that the detected population is small. None the less it is striking that these three outbursts were all discovered by *Swift* in the space of a 3 month window in 2011. At first sight it may be argued that the proximity, and consequent brightness, of Swift J1644+57 may have motivated the searches that led to the discoveries of the additional candidates. However, the lack of any further examples in the subsequent four years suggests that this is more likely a statistical fluke. It is possible to quantify this via an archival search of *Swift* GRBs and the BAT transient monitor (Krimm et al. 2013). Within the 6.5 yr of data reported in Krimm et al. (2013) there are two events marked as TDFs (the previously identified bursts), while only a further three are marked as ‘unknown’. Two of these (Swift J1713.4–4219, IGR J17361–4441) lie close to the Galactic plane, and are most likely Galactic sources. This leaves only the source under discussion, Swift J1112–8238, as a candidate relativistic TDF. It is plausible, though, that some other sources within the

catalogue have been misidentified. In particular, Swift J1644+57 was initially identified as a Galactic Fast X-ray Transient (Kennea et al. 2011). However, the population detected by the BAT transient monitor is necessarily small.

In total, therefore, it appears that at most a handful of such events have been recorded over *Swift*'s ~ 9 yr lifetime. Similar to Cenko et al. (2012b), we can determine an implied analogous (i.e. similar *isotropic* luminosity) relativistic TDF rate based on the three events observed in ~ 10 yr, using the volume bounded by the distance to Swift J2058+05, as the most distant yet observed at $z = 1.1853$ giving a comoving volume of 215 Gpc^3 , and assuming the local number density of $10^6\text{--}10^8 M_\odot$ SMBHs to be 10^{-2} Mpc^{-3} (Tundo et al. 2007). The resulting rate is found to be $\sim 3 \times 10^{-10}$ per galaxy per year, in stark contrast to the $\sim 10^{-5}$ inferred from thermal TDF detections (e.g. Donley et al. 2002; van Velzen & Farrar 2014). Even if a significant fraction of the ULGRB population were related to similar phenomena this would be unlikely to constitute the majority of the factor of 3×10^4 required. To resolve this discrepancy likely requires a combination of tightly beamed high-energy emission, such as that seen in GRBs, and that not all TDFs produce relativistic jets.

Recent late-time radio surveys of thermal TDFs by Bower et al. (2013) suggest that ~ 10 percent of TDFs may have an associated relativistic jet. Given this, the required beaming angle for rTDF high-energy emission would be of the order of 1° . At first sight this is not unreasonable, given that, for example, Swift J1644+57 produced an isotropic X-ray emission equivalent to the Eddington luminosity of a $10^{10} M_\odot$ black hole in a galaxy that is only expected to contain an SMBH of $\sim 10^6$ solar masses (Bloom et al. 2011; Levan et al. 2011). In this case beaming (either relativistic and/or geometric) of a factor 10^4 , or highly super-Eddington accretion would seem to be necessary. However, radio observations of Swift J1644+57 point to a rather modest Lorentz factor, that would be unlikely to result in such strong collimation ($\Gamma \sim 2$; Zauderer et al. 2011), unless the radio and high-energy emission regions are spatially separate, each with their own Lorentz factors. It is also possible that the survey of Bower et al. (2013) could be impacted by small number statistics and potential contaminants. One of the two detections made, RXJ1420.4+5334 has an uncertain host identification due to the large error in the X-ray flare position. The second, IC3599, may be an AGN (Grupe et al. 1995), and has recently exhibited repeated flares, either due to repeated partial disruptions of the same star on an ~ 10 yr orbit (Campana et al. 2015) or due to ongoing AGN activity (Grupe, Komossa & Saxton 2015). Because of this, the suggested 10 percent jetted TDF fraction may be over-estimated, which would explain the lack of detections in any of the other studies (e.g. Arcavi et al. 2014), thus further contributing to the apparent deficit of detected rTDFs. Clearly further observations of larger samples of sources across the electromagnetic spectrum are needed to resolve this question.

5 SUMMARY

We have presented multiwavelength observations of Swift J1112–8238, pinpointing it to close to the nucleus of an otherwise quiescent galaxy at $z = 0.89$. The high X-ray luminosity of the source coupled with its relative optical faintness occupy a region of parameter space which is populated only by the candidate relativistic TDFs. Hence we suggest that Swift J1112–8238 is the third candidate member of this class of events as detected by their high-energy emission. The discovery of such a small number of events over the lifetime of *Swift* suggests that they are extremely rare and

that, unless the beaming angles are extremely small (evidence for which may come from the extreme observed luminosities coming from events in hosts with small expected SMBHs), then their true astrophysical rates are also only a small fraction (about 1 in 10^5) of the likely non-relativistic TDF rate. The factors which govern the production of a relativistic outflow associated with a given TDF remain unclear, but highlight the needed for rapid dedicated follow-up of the rare examples when they are found.
