## Abstract

Non-human primates, differently from humans, are less proficient at processing global properties of visual compound stimuli. It has been suggested that humans preferentially process stimuli globally because this enables a more economical encoding of the stimuli. In this study we assessed the role of short-term memory in global/local processing by presenting tufted capuchin monkeys with Navon-type hierarchical figures in both simultaneous and delayed matching-to-sample tasks. Capuchins' ability to discriminate hierarchical stimuli was evaluated as a function of increasing delay intervals (0.0, 0.5, 1.0, 2.0 and 3.0 sec) between the disappearance of the sample and the presentation of the comparison stimuli. The results showed that recognition accuracy for local features was above chance level with delays of up to 3.0 sec, as previously reported when capuchins were faced with non-hierarchical stimuli. By contrast, the recognition of global configurations was above chance level in simultaneous, 0.0 and 0.5 sec delay conditions but not at delay intervals of 1.0 sec or longer. These findings indicate that capuchins' propensity to process the local properties of visual stimuli can be observed when a delay is interposed between the presentation of sample and comparison stimuli and was not reversed by increasing the delay. Moreover, our results show that capuchins' local propensity was not reversed by increasing stimulus size. Overall, our study confirms crucial differences between human and non-human primates and adds new insights into the comparative research on visual grouping functions of these species.

## Introduction

30

31 In order to visually identify objects and segregate them from the background, we  
32 must be able to group their component elements into a coherent perceptual whole  
33 (Kimchi, Beherman & Olson, 2003). Many studies on visual grouping are focused on the  
34 ability to process hierarchical stimuli, i.e. small (local) shapes arranged to form large  
35 (global) shapes. By using these stimuli, Navon (1977) found that adult humans were  
36 faster at identifying global shapes than local features and proposed that the global  
37 properties of a visual object are processed first, followed by an analysis of local  
38 constituents (Navon, 1977, 1981). This hypothesis, called the ‘global precedence  
39 hypothesis’, has been widely confirmed in the human literature (e.g., Kimchi, 1992,  
40 1998; Lamb, Robertson, & Knight, 1990). Nevertheless, global preference seems to  
41 decrease with the increase of either stimulus size (Kinchla & Wolfe, 1979; Lamb &  
42 Robertson, 1988) or the distance between the elements composing the global  
43 configuration (Martin, 1979).

44 Comparative research on global/local processing of hierarchical stimuli has been  
45 conducted on a number of non-human species including fish (Truppa, Sovrano, Spinozzi,  
46 & Bisazza, 2010), birds (pigeons: Cavoto & Cook, 2001; Fremouw, Herbranson, &  
47 Shimp, 1998, 2002; Goto, Wills, & Lea, 2004; domestic chicks: Chiandetti, Pecchia,  
48 Patt, & Vallortigara, 2014), mammals (domestic dogs: Pitteri, Mongillo, Carnier, &  
49 Marinelli, 2014; primates: Deruelle & Fagot, 1998; Fagot & Deruelle, 1997; Fagot &  
50 Tomonaga, 1999; Hopkins & Washburn, 2002; Neiworth, Gleichman, Olinick, & Lamp,  
51 2006; Spinozzi, De Lillo, & Truppa, 2003; Tanaka & Fujita, 2000; Tanaka, Onoe,  
52 Tsukada, & Fujita, 2001). Notably, differences found in global/local processing between

53 human and non-human primates raised intriguing questions because of similarities in  
54 neuroanatomical correlates of visual functions in these species.

55 An unresolved problem in visual cognition is the reason why the well-established  
56 advantage shown by humans in the processing of global properties of visual patterns is  
57 not present in other primates species which nevertheless share very similar visual  
58 systems (e.g., Fobes & King, 1982; Kremers, 2005; Ungerleider & Mishkin, 1982).  
59 Whereas humans are faster at identifying the global configuration compared to the local  
60 elements, monkey species, in most cases, process the local components of hierarchical  
61 patterns more proficiently than their global structure (capuchins: De Lillo, Spinozzi,  
62 Palumbo, & Giustino, 2011; De Lillo, Palumbo, Spinozzi, & Giustino, 2012; Spinozzi et  
63 al., 2003; Spinozzi, De Lillo, & Salvi, 2006; baboons: Deruelle & Fagot, 1998; Fagot &  
64 Deruelle, 1997; macaques: Hopkins & Washburn, 2002; for different results see  
65 Neiwirth et al., 2006; Tanaka & Fujita, 2000; Tanaka et al., 2001). On the other hand,  
66 chimpanzees, in contrast with monkeys, do not always process the local features of the  
67 compound patterns better than their global shape (Fagot & Tomonaga, 1999; Hopkins &  
68 Washburn, 2002). This possible relationship between phylogenetic distance from humans  
69 and the emergence of a clear global advantage could be of significant interest for the  
70 explanation of human cognitive evolution. According to some authors, these results can  
71 reflect a greater difficulty of monkeys compared with humans in grouping the local  
72 elements into a coherent whole rather than a local advantage *per se* (Fagot & Barbet,  
73 2006). Nevertheless, in contrast with humans, capuchin monkeys process at a higher  
74 level of accuracy the local levels of hierarchical visual stimuli that are specifically  
75 designed to require grouping at both levels of stimulus structure (De Lillo et al., 2012).

76 Also, results showing that monkeys can be resistant to visual illusions requiring the  
77 processing the relationship between parts of a visual image have been put in relation to

78 their local mode of processing. Conversely, a global mode of processing makes humans  
79 sensitive to these illusions (Parron & Fagot, 2007).

80 It has been claimed that the tendency of humans to process the global level of  
81 stimulus structure first, supports the efficient and economic storage of information  
82 (Navon, 1977). This notion would be consistent with the proposal that human cognition  
83 strives to achieve the simplest form of stimulus coding (Chater, 1996; 1997). The fact  
84 that monkeys, with whom humans share several homologous brain areas, do not seem to  
85 show the same tendency raises important theoretical issues regarding when and why  
86 data-reducing cognitive mechanisms started to emerge in primate cognitive evolution.

87 The sensitivity of monkeys to properties of visual stimuli that can potentially be  
88 exploited by data-reducing cognitive mechanisms, such as the degree of redundancy of  
89 their structure, is debatable. Early studies have failed to show an ability to detect  
90 redundancy in visual stimuli in macaques (Schrier, Povar, & Schrier, 1979). More recent  
91 studies, however, show that capuchin monkeys can be sensitive to the redundancy of  
92 visual patterns (De Lillo et al., 2012).

93 It seems that higher processes in monkeys' visual cognition are involved in  
94 determining their preference for processing the local details of visual stimuli. In fact, it is  
95 possible to reverse the local advantage of capuchin monkey by inducing subjects to  
96 attend the global level of visual stimuli (De Lillo et al., 2011). The inversion of the local  
97 advantage determined by directing the attention of capuchin monkeys to global  
98 properties of the stimuli, however, is due to changes that negatively affect the quality of  
99 processing of local details of stimuli, whereas the quality of processing of their global  
100 shape remains unaffected by manipulations of attention bias. Thus, it has proved difficult  
101 to find the conditions that may ameliorate the ability of monkeys to efficiently process  
102 global properties of hierarchical visual stimuli.

103        Yet, in order to determine if genuine differences exist in data-reducing cognitive  
104 devices of different primate species it is important to be able to rule-out that under  
105 appropriate circumstances monkeys can show the same degree of data reduction abilities  
106 shown by humans, and possibly chimpanzees. In fact, it is possible that monkeys would  
107 deploy data reducing strategies in visual cognition when provided with enough incentive  
108 to do so.

109        Comparative studies so far have used forms of matching-to-sample (MTS) in which  
110 participants are required to choose which of two comparison stimuli resembles most  
111 closely a stimulus presented as sample without any delays interposed between the  
112 presentation of the sample and the comparison stimuli (either simultaneous MTS or 0-  
113 delay MTS) (e.g., De Lillo et al., 2011, 2012; Fagot & Deruelle, 1997; Hopkins &  
114 Washburn, 2002; Spinozzi et al 2003, 2006). In simultaneous matching-to-sample  
115 (SMTS), the sample stimulus remains on the screen when the comparison stimuli are  
116 presented. In 0-delay matching-to-sample (DMTS), the sample stimulus disappears  
117 simultaneously with the presentation of the comparison stimuli. With these types of  
118 MTS, participants may not need to encode the stimuli in capacity bound memory stores  
119 (i.e., short- and long-term memory stores) because the stimuli can be available either  
120 perceptually or as part of large capacity sensory (iconic) memory (Averbach & Coriell,  
121 1961; Sperling, 1960; Neisser, 1967). Therefore, the incentive for an economic encoding  
122 of global configurations, rather than disconnected features, would be minimal. There is  
123 also a second reason for predicting that global processing could be facilitated in delayed  
124 MTS. Influential approaches to visual perception (Milner & Goodale, 2006) suggest that  
125 the dorsal cortical visual system has the function of connecting sensory and motor  
126 information in order to allow rapid and efficient actions towards perceived objects. Such  
127 system would rely on egocentric co-ordinates that provide accurate information

128 regarding the position of the observer and the object that needs to be acted upon but  
129 would not encode relationships between parts of a visual scene. Processing within the  
130 dorsal visual stream operates on a rapid timescale supporting actions performed within  
131 2.0 sec of the appearance of visual objects. Experiments that have compared fast actions  
132 directed to objects in the visual field and pantomimed action performed after visual  
133 objects have disappeared for 2.0 sec have shown striking differences in patterns of  
134 results. Only pantomimed actions, such as grasping for visual objects, are sensitive to  
135 visual illusions that require the processing of the relationships between different parts of  
136 the visual scene. Thus grip aperture, when attempting to grasp visual objects presented  
137 within contexts known to illusorily affect their perceived size, is only distorted when a  
138 delay of 2.0 sec is imposed between object presentation and motor response (Goodale,  
139 Jakobson, & Keillor, 1994; Aglioti, DeSouza, & Goodale, 1995; Milner & Goodale,  
140 2008). These results are interpreted as indicating an involvement of the ventral visual  
141 system that allows the perception of the relations of stimulus parts, only for arbitrary  
142 and/or delayed responses to visual stimuli (Aglioti et al., 1995; Milner & Goodale,  
143 2008).

144 Most experiments of global/local processing in capuchin monkeys so far have  
145 involved immediate responses to visual stimuli, often consisting in displacing three  
146 panels depicting the stimuli in a Wisconsin General Test Apparatus - WGTA (see  
147 Spinozzi et al., 2003; De Lillo et al., 2011). It is therefore possible that this method for  
148 presenting stimuli and collecting responses induced the subjects to rely mostly on the  
149 dorsal visual system that is not best suited to process the relationship between parts of a  
150 visual image. Imposing a delay between stimulus presentation and response may, by  
151 contrast, force the subjects to recruit ventral visual functions more sensitive to relational  
152 processing. In fact, the dorsal system, that is likely to be less sensitive to relational

153 properties of visual input given its reliance on egocentric co-ordinates, support actions  
154 performed towards visual objects within fractions of seconds. Hence, delayed responses  
155 (typically of 2 seconds, see Milner and Goodale, 2006) towards objects that are no longer  
156 visually available are used to ensure that the response is informed by a visual  
157 representation of the stimulus created by ventral stream processing. As the ventral stream  
158 relies on allocentric co-ordinates it is better suited to compute the relationship between  
159 different parts of a visual image.

160 Thus, it is possible that delayed MTS could provide an incentive to integrate parts in  
161 wholes and tap the visual system most suitable for doing so. Testing capuchin monkeys  
162 with delayed MTS is therefore important to determine the constraints under which the  
163 local advantage in monkeys could be reversed.

164 Recently, Truppa, De Simone, Piano Mortari, and De Lillo (2014) using a  
165 computerised procedure demonstrated that, although the introduction of very brief time  
166 intervals (up to 3.0 sec) in delayed matching-to-sample tasks did not prevent capuchin  
167 monkeys' ability to solve the task with non-hierarchical visual stimuli, it can affect  
168 recognition performance. Specifically (1) the simple disappearance of the sample and the  
169 introduction of a delay of 0.5 sec did not affect capuchins' recognition of the stimuli, (2)  
170 a delay interval of 1.0 sec produced a significant increase in response time but still did  
171 not affect recognition accuracy, and (3) delays of 2.0 and 3.0 sec determined a significant  
172 increase in response time and a reduction in recognition accuracy. These results indicate  
173 that shorter or longer delays around 2 sec produce non-linear effects on MTS  
174 performance in capuchin monkeys, which could be an expression of different types of  
175 processing. To evaluate how delays affect global/local processing in capuchin monkeys,  
176 in the present study we tested their ability to match hierarchical stimuli on the basis of  
177 global shapes or local features when: (i) the sample stimulus was always available on the

178 screen until subjects made a choice (SMTS); (ii) the sample disappeared with no delay in  
179 the presentation of the comparison stimuli (0-delay MTS); or (iii) different delays (0.5,  
180 1.0, 2.0 and 3.0 sec) between the disappearance of the sample and the availability of the  
181 comparison stimuli were introduced (DMTS). If local elements are better preserved than  
182 global configuration independently of delay length, this could suggest a substantially  
183 different mode of encoding visual information in monkeys and humans. By contrast, if  
184 the local preference of capuchins could be reversed by increasing the need for efficient  
185 memory storage and/or by requiring the engagement of a different visual processing  
186 system this would suggest a more similar mode of processing in humans and monkeys  
187 than suggested by previous studies.

188 Taking advantage of a computerised procedure, which allowed a highly controlled  
189 presentation of the stimuli, we also assessed whether or not the local advantage of  
190 capuchins could be affected by stimulus size and order of presentation of global and local  
191 trials. Stimulus size was manipulated because early studies with humans suggested that it  
192 can affect the global precedence effect in humans (Kinchla & Wolfe, 1979). The role  
193 stimulus size has been considered confounded with effects related to the eccentricity of  
194 the stimuli in humans (Navon & Norman, 1983) and previously proved to be unable to  
195 reverse the local advantage typically shown by capuchin monkeys (Spinozzi et al., 2006),  
196 as well as the global advantage shown by fish (Truppa et al., 2010). Nevertheless, it was  
197 considered important to assess its role in a paradigm that involved delayed MTS. The  
198 order of presentation of global and local trials was manipulated because effects of the  
199 context of trials in which MTS occurs sometimes can affect performance (Truppa et al.,  
200 2014) and, to our knowledge, the effect of context provided by the order of presentation  
201 has not been assessed on capuchin monkeys before. Thus, it was considered important to  
202 assess the effects of this additional variable here.

215

216

217

Subjects were four tufted capuchin monkeys (*Sapajus*<sup>1</sup> spp.), two males (Robot and Sandokan) and two females (Roberta and Rucola). All subjects were adults (age: 11-25 years old) born in captivity and hosted at the Primate Center of the Institute of Cognitive Sciences and Technologies, CNR, Rome, Italy. They lived in three groups, each housed in an indoor-outdoor enclosure (indoor: 5 m<sup>2</sup> x 2.5 m high; outdoor: 40-130 m<sup>2</sup> x 3 m high). The monkeys were individually tested in an adjacent experimental cage (0.76 m long x 1.70 m wide x 0.73 m high), that they could access through a sliding door. Each subject was separated from the group just before the daily testing session solely for the purpose of testing. The testing occurred between 10:30 a.m. and 4:00 p.m. Water was freely available at all times. Fresh fruit, vegetables and monkey chow were provided in the afternoon after testing.

218

222

223

All monkeys were already familiar with the matching-to-sample procedure because they had been tested with a touchscreen based apparatus in tasks involving abstract concept acquisition and short-term memory effects (Truppa et al., 2014; Truppa, Garofoli et al., 2010; Truppa, Piano Mortari, Garofoli, Privitera, & Visalberghi, 2011). However, subjects had never been tested with Navon-type hierarchical figures before.

---

<sup>1</sup> On the basis of recent data, it has been proposed that capuchin monkey species, traditionally identified as belonging to a single genus (*Cebus*), can be grouped instead in two distinct genera: (i) the robust (tufted) forms have been referred to the genus *Sapajus*, and (ii) the gracile (untufted) forms have been retained in the genus *Cebus* (Lynch Alfaro, Boubli et al., 2012; Lynch Alfaro, De Souza Silva, & Rylands, 2012). Tufted capuchin monkeys hosted at the Primate Center of the CNR are derived from individuals of different provenience and are considered to be unknown combinations of species of the genus *Sapajus*.

224        **Ethical note**

225        The research protocol used in this study was approved by the Italian Health Ministry  
226 (Central Direction for the Veterinary Service, approvals n. 11/2011-C to V. Truppa).  
227 Housing conditions and experimental procedures were in full accordance with European  
228 law on humane care and use of laboratory animals and complied with the  
229 recommendations of the Weatherall Report (2006). To increase three-dimensional space  
230 available to the animals, indoor enclosures were furnished with perches and ropes and  
231 outdoor enclosures were furnished with logs, branches and ropes. Moreover, the presence  
232 of natural substrates, including woodchips on the ground, served to promote the  
233 monkeys' exploratory behaviours. All subjects were habituated to the experimental cage,  
234 the experimental routine and the experimenters.

235

236        **Apparatus**

237        The computerised workstation consisted of a PC (Model AMD Athlon 1200)  
238 connected to a 19" touchscreen (Model E96f+SB, CRT, ViewSonic) and an automatic  
239 food dispenser (Model ENV-203-45, MED Associates, Inc. Georgia, VT) (Figure 1A).  
240 When the monkey provided the correct response, the food dispenser delivered a 45-mg  
241 banana-flavoured pellet (TestDiet, Richmond, IN, USA) into a Plexiglas feeding cup (10  
242 cm wide x 5 cm deep x 3.5 cm high) located 16 cm below the touchscreen, in the centre.  
243 E-Prime software (Psychology Software Tools, Inc.) was used for the presentation of the  
244 stimuli, the recording of the subject's response and the activation of the food dispenser.

245        A wooden frame (48 cm wide x 64 cm high x 30 cm deep) with a central aperture  
246 (36 cm wide x 26 cm high) surrounded the touchscreen. The food dispenser was placed  
247 behind the wooden frame, out of sight of the subject. Moreover, an additional LCD  
248 monitor was placed at the back of the touchscreen to allow the experimenter to see the

249 progress of the session so as to remove the apparatus at the end of the session. The  
250 touchscreen, food dispenser and additional LCD monitor were mounted on the top shelf  
251 of a trolley (81 cm long x 45 cm wide x 80 cm high), whereas the PC was on the bottom  
252 shelf.

253 The apparatus was placed 15 cm from the grid of the experimental cage within the  
254 arm's reach of the subject. The grid was made of horizontal metal bars (0.5 cm thick)  
255 that were separated by 4.5 cm.

256 A camcorder (Sony Handycam DCR-SR37) was positioned approximately 70 cm  
257 from the touchscreen monitor in order to record video images which included both the  
258 screen display and a back view of the monkey. This allowed the experimenters to  
259 videotape the subject's behaviour during testing.

260

## 261 **Stimuli**

262 Two stimulus sets, each of 16 compound forms were used (Figure 1B). Each set  
263 included large circles, squares, rhombi, or letter Xs made up of smaller circles, squares,  
264 rhombi, or letter Xs. We label these stimuli as Cc, Cs, Cr, Cx, Ss, Sc, Sr, Sx, Rr, Rc, Rs,  
265 Rx, Xx, Xc, Xs, and Xr, indicating with the first letter the global shape and with the  
266 second one the local shape (e.g., Cs refers to a large circle made of small squares).  
267 Moreover, each set included four consistent figures (Cc, Ss, Rr, and Xx), where global  
268 and local shapes were the same and 12 inconsistent figures (Cs, Cr, Cx, Sc, Sr, Sx, Rc,  
269 Rs, Rx, Xc, Xs, and Xr), in which global and local shapes were different. Each stimulus  
270 consisted of 12 white elements, however the size of both local elements and global  
271 configurations varied between the two stimulus sets. The Set A, included 0.50 cm x 0.50  
272 cm (i.e., 1.91° of visual angle) local elements spatially arranged to form 4 cm x 4 cm  
273 (i.e., 14.93° of visual angle) global shapes. The distance between two adjacent elements

274 was 0.66 cm (i.e., 2.52° of visual angle). The Set B, included 0.25 cm x 0.25 cm (i.e.,  
275 0.95° of visual angle) local elements spatially arranged to form 2 cm x 2 cm (i.e., 7.59°  
276 of visual angle) global shapes. The distance between two adjacent elements was 0.33 cm  
277 (i.e., 1.26° of visual angle). The sizes of the stimuli included in Set A and B mimicked  
278 conditions used with capuchin monkeys by Spinozzi et al. (2003). These authors used 4  
279 cm x 4 cm hierarchical stimuli (same size of our Set A), which at the beginning of the  
280 trials were presented at a distance of 30 cm (i.e., 7.59° of visual angle, a condition we  
281 replicated by using Set B) and then moved within the monkey's reach at a distance of 15  
282 cm (i.e., 14.9° of visual angle, a condition we replicated by using Set A).

283 Stimuli were all presented within a black background (6.5 cm x 6.5 cm, i.e. 23.4° of  
284 visual angle). They were created using Microsoft PowerPoint and were transformed into  
285 bitmap images for stimulus presentation on the computer screen.

286

### 287 **Procedure**

288 An MTS task was used, in which three stimuli, the sample stimulus (SS), the  
289 matching - rewarded - stimulus (S+), and the non-matching stimulus (S-), were presented  
290 on the computer screen. At the beginning of each trial, SS was automatically generated  
291 on the upper half of the screen, in the centre. Then, after the subject touched the sample  
292 stimulus one time, S+ and S- were displayed simultaneously 4 cm below the sample, to  
293 the right and left, at a distance of 5 cm apart (Figure 1A). The initial touch to the sample  
294 ensured that the monkey was paying attention to the sample stimulus at the beginning of  
295 each trial. Depending on the experimental condition, the sample could either remain  
296 present when the comparison stimuli appeared (SMTS) or disappear immediately after  
297 that the subject touched it (DMTS). In the DMTS different delay intervals were  
298 interposed between the disappearance of the sample and the appearance of the

299 comparison stimuli (0.0, 0.5, 1.0, 2.0, 3.0 sec). The right/left position of S+ and S- was  
300 randomly determined for each trial. The subject had to indicate its choice by touching  
301 one of the comparison stimuli on the screen (see supplemental videos: S1, S2, S3 and  
302 S4); the computer automatically recorded the choice and the Response Time (RT) to  
303 make the choice. If S+ was chosen, a food pellet was dispensed. If S- was selected, no  
304 pellet was dispensed. The display disappeared immediately after a response was  
305 recorded. A correct response was followed by a 5-s inter-trial interval (ITI), whereas an  
306 incorrect response was followed by both a 10-s time-out (TO) and a 5-s ITI. During the  
307 experimental trials and the ITI, the screen was light grey; during the TO, the screen was  
308 green.

309

### 310 **Experimental design**

311 All monkeys were tested with stimuli of Set A (larger stimuli) first and then with  
312 stimuli of Set B (smaller stimuli). For each stimulus set, the monkeys were faced with  
313 two different matching conditions. In the Global condition, S+ was identical to the  
314 sample and S- differed from the sample only at its global level. For example, a trial of  
315 the global condition featuring stimulus Rr (see Figure 1B) as the sample would have  
316 stimulus Rr presented as S+ and could have stimulus Cr presented as S-. In the Local  
317 condition, S+ was identical to the sample and S- differed from the sample only for the  
318 shape of its local elements. In this case, a trial featuring stimulus Rr as the sample would  
319 have stimulus Rr presented as S+ and could have stimulus Rs presented as S-. Each  
320 subject received 24 48-trial sessions (12 for each stimulus set), one session a day for a  
321 total of 1152 trials. Overall, each type of stimulus ( $n = 16$ ) was presented as sample for a  
322 total of 6 trials for each level of processing ( $n = 2$ : global, local) in each matching  
323 condition ( $n = 6$ : simultaneous, 0.0, 0.5, 1.0, 2.0, 3.0 sec). For each stimulus set: (1) six

324 sessions (intermixed global/local session) included 24 Global trials and 24 Local trials  
325 presented in a pseudo-random order, with the only constraint that trials of the same  
326 condition (global or local) were presented no more than two times consecutively; (2)  
327 three sessions (blocked global sessions) included 48 Global trials; and (3) three sessions  
328 (blocked local sessions) included 48 Local trials. All sessions included five 8-trial blocks  
329 with different delays (0.0, 0.5, 1.0, 2.0, 3.0 sec) and one 8-trial block of simultaneous  
330 MTS. Trials of the six conditions were randomly intermixed within each session. The  
331 three types of session (intermixed global and local, blocked global, blocked local) were  
332 alternated according to an order of presentation which was different for each subject.

333

#### 334 **Data analyses**

335 The percentage of correct responses and the mean RT were used for the analyses.  
336 RT was measured as the time between the appearance of the comparison stimuli and the  
337 subject's choice (i.e., the touch of a comparison stimulus). Only RTs for correct choices  
338 were included in the analyses. The videos of the experimental sessions were used to  
339 detect instances where the subject turned away from the screen during a trial, thus  
340 spuriously affecting the length of the delay interval between the appearance of the  
341 comparison stimuli and the subjects' response. All trials where such instances were  
342 detected were removed from those analyses.

343 Because the Kolmogorov-Smirnov test showed that the distribution of data did not  
344 deviate from normality, we used parametric statistics to compare the accuracy scores and  
345 response times between different conditions. For each test variable, a one-sample *t*-test  
346 was used to compare the observed percentage of correct responses of capuchins with the  
347 percentage expected by chance (i.e., 50%). Repeated measures ANOVAs were used to  
348 compare different conditions both in terms of percentage of correct responses and mean

349 RTs. Finally, post-hoc tests (Tukey, HSD test) for multiple comparisons were used to  
350 further analyse significant effects revealed by the ANOVAs. Statistical significance was  
351 set at  $p \leq .05$ .

352

353

## Results

354

355 The analyses of the videos revealed that in 249 trials (5.4% of all trials) subjects were  
356 not looking at the screen when the comparison stimuli appeared (Rucola = 100,  
357 Sandokan = 37, Robot = 41, Roberta = 71). In the simultaneous and 0-delay conditions  
358 this was a very rare event, which occurred only 8 and 10 times, respectively. However,  
359 this happened more frequently with the increasing of the length of the delay (Spearman  
360 correlation,  $r = .94$ ,  $N = 6$ ,  $p = .005$ ). Moreover, this happened with a similar frequency  
361 in the local [ $M = 18.2$ , 95%  $CI$  (9.12, 27.38)], and global trials [ $M = 15.5$ , 95%  $CI$  (4.44,  
362 26.56)], [paired t-test:  $t(3) = 1.36$ ,  $p = .266$ ] of the blocked sessions. This latter analysis  
363 was only carried out for the blocked sessions. In fact, it would have been meaningless in  
364 the intermixed sessions. This is because in the intermixed sessions, the subjects did not  
365 have any information regarding whether the trial pertained to the local or global  
366 condition in the interval between the presentation of the sample and the comparison  
367 stimuli.

368 The trials in which subjects were not looking at the screen when the comparison  
369 stimuli appeared featured an uncontrolled increase of the scheduled interval, therefore  
370 they were not subjected to any further analysis.

371

372 *Accuracy.* Table 1 reports the results of one-sample  $t$ -tests for the local and global  
373 trials in each matching condition (SMTS, 0.0, 0.5, 1.0, 2.0, 3.0 sec delayed). In the local

374 trials, capuchins' percentage of correct responses was significantly above the level of  
375 chance (50%) in all different conditions. By contrast, in the global trials the percentage  
376 of responses was above chance level only in the SMTS condition, the 0-delay MTS  
377 condition and when the delay was 0.5 sec. Longer delays induced chance-level  
378 performance (see Figure 2).

379 An ANOVA was carried out on the percentage of correct responses with delay  
380 condition (simultaneous, 0.0, 0.5, 1.0, 2.0, 3.0 sec delayed), level of processing (global,  
381 local), stimulus size (larger, smaller), stimulus consistency (consistent, inconsistent), and  
382 trial order (global and local intermixed, global and local blocked) as repeated measures.  
383 The analysis revealed a significant main effect of the delay condition [ $F_{(5, 15)} = 6.1, p =$   
384  $.003, \eta p^2 = .670$ ] and significant interactions between: (1) delay condition and trial order  
385 [ $F_{(5, 15)} = 4.4, p = .011, \eta p^2 = .595$ ], (2) level of processing and trial order [ $F_{(1, 3)} = 50.5,$   
386  $p = .006, \eta p^2 = .944$ ], and (3) level of processing and stimulus size [ $F_{(1, 3)} = 26.5, p =$   
387  $.014, \eta p^2 = .898$ ]. No other significant main effects or interactions were found (all  $ps >$   
388  $.058$ ).

389 Post-hoc analyses (Tukey, HSD test) for the interaction between delay condition and  
390 trial order indicated that accuracy in different delay conditions varied according to the  
391 order of presentation of global and local trials (see Figure 3). When global and local  
392 trials were presented in blocked sessions the mean percentage of correct responses  
393 observed in simultaneous [ $M = 67.53\%$ , 95%  $CI (57.71, 77.36)$ ], 0.0 sec [ $M = 66.23\%$ ,  
394 95%  $CI (45.55, 86.92)$ ], 0.5 sec [ $M = 65.71\%$ , 95%  $CI (54.93, 76.49)$ ], 1.0 sec [ $M =$   
395  $67.27\%$ , 95%  $CI (55.21, 79.34)$ ] and 2.0 sec [ $M = 60.10\%$ , 95%  $CI (40.37, 79.77)$ ] delay  
396 conditions did not differ from each other. Capuchin' accuracy in simultaneous, 0.0, 0.5  
397 and 1.0 sec delay conditions was significantly higher than that of the 3.0 [ $M = 55.06\%$ ,  
398 95%  $CI (38.72, 71.40)$ ], (all  $ps < .028$ ); moreover the percentage of correct responses

399 observed in the 2.0 and 3.0 sec delay conditions did not differ. When global and local  
400 trials were intermixed in the same session the mean percentage of correct responses  
401 observed in the simultaneous [ $M = 71.35\%$ , 95%  $CI$  (62.13, 80.58)], 0.0 sec [ $M =$   
402 72.65%, 95%  $CI$  (60.37, 84.94)] and 0.5 sec [ $M = 70.31\%$ , 95%  $CI$  (62.02, 78.60)] delay  
403 conditions did not differ from each other. By contrast, the percentage of correct  
404 responses recorded in all these conditions was significantly higher than that observed in  
405 the 1.0 sec [ $M = 58.59\%$ , 95%  $CI$  (47.48, 69.70)], 2.0 sec [ $M = 61.20\%$ , 95%  $CI$  (44.38,  
406 78.01)] and 3.0 sec [ $M = 58.33\%$ , 95%  $CI$  (49.88, 66.78)] delay conditions, (all  $ps <$   
407 .040). Finally the level of response accuracy of the 1.0, 2.0 and 3.0 sec delay conditions  
408 did not differ from each other. The interaction is most likely explained by the fact that  
409 MTS performance in the blocked condition seems to deteriorate at 2 sec delay. By  
410 contrast, in the intermixed condition a deterioration of MTS performance starts to occur  
411 at 1 sec interval.

412 Post-hoc analyses for the interaction between level of processing and trial order  
413 indicated that the level of accuracy was significantly higher in local than global trials  
414 irrespectively of whether the two types of trials were intermixed [local:  $M = 74.22\%$ ,  
415 95%  $CI$  (56.54, 91.89); global:  $M = 56.60\%$ , 95%  $CI$  (51.39, 61.80);  $p = .0007$ ] or  
416 blocked [local:  $M = 68.79\%$ , 95%  $CI$  (48.26, 89.32); global:  $M = 58.51\%$ , 95%  $CI$   
417 (48.39, 68.62);  $p = .002$ ] (see Figure 4). Moreover, whereas in local trials the percentage  
418 of correct responses was significantly higher when the two types of stimuli were  
419 intermixed than when they were blocked ( $p = .015$ ), in global trials there was no  
420 difference between the two types of presentation order ( $p = .215$ ).

421 Finally, post-hoc analyses for the interaction between level of processing and  
422 stimulus size indicated that, although the level of accuracy was always higher in local  
423 than global trials, this advantage was significant with larger stimuli [local:  $M = 75.35\%$ ,

424 95% *CI* (61.27, 89.43); global:  $M = 53.50\%$ , 95% *CI* (46.25, 60.75);  $p = .006$ ] but not  
425 with smaller stimuli [local:  $M = 67.66\%$ , 95% *CI* (42.48, 92.84); global:  $M = 61.60\%$ ,  
426 95% *CI* (52.63, 70.57);  $p = .188$ ] (see Figure 5). Moreover, the mean percentage of  
427 correct responses in local trials with larger stimuli did not differ from that of local trials  
428 with smaller stimuli ( $p = .109$ ). Likewise, the accuracy in global trials with larger stimuli  
429 did not differ with that observed in global trials with smaller stimuli ( $p = .096$ ).

430

431 *Response time.* An ANOVA was carried out on the RT for correct responses with  
432 delay (simultaneous, 0.0, 0.5, 1.0, 2.0, 3.0 sec delay), level of processing (global, local),  
433 stimulus size (larger, smaller), stimulus consistency (consistent, inconsistent), and trial  
434 order (intermixed, blocked) as repeated measures factors. A significant main effect of  
435 delay was found [ $F(5, 15) = 7.6$ ,  $p = .0009$ ,  $\eta p^2 = .718$ ]. No other significant main effects  
436 or interactions were found (all  $ps > .076$ ).

437 Post-hoc comparisons on the main effect of delay revealed that the mean RT of the  
438 Simultaneous condition [ $M = 1324.43$  msec, 95% *CI* (830.26, 1818.60)] did not differ  
439 from the 0.0 [ $M = 1237.59$  msec, 95% *CI* (703.93, 1771.24),  $p = .747$ ], 0.5 [ $M = 1416.71$   
440 msec, 95% *CI* (885.90, 1947.52),  $p = .699$ ], 1.0 [ $M = 1489.50$  msec, 95% *CI* (1023.78,  
441 1955.23),  $p = .160$ ] and 2.0 [ $M = 1523.61$  msec, 95% *CI* (1065.48, 1981.73),  $p = .063$ ]  
442 sec conditions but it was significantly shorter than in the 3.0 sec delay condition [ $M =$   
443 1560.79 msec, 95% *CI* (1087.59, 2033.99),  $p = .021$ ]. The mean RT in the 0.0 sec  
444 condition was significantly shorter than in the 1.0 ( $p = .013$ ), 2.0 ( $p = .005$ ) and 3.0 ( $p =$   
445 .002) sec of delay. Finally, the RT for the 0.5, 1.0, 2.0 and 3.0 sec delay conditions did  
446 not significantly differ from each other (all  $ps > .268$ ).

447

448

## Discussion

449

450 This study demonstrated that capuchins monkeys are able to discriminate hierarchical  
451 figures in delayed matching-to-sample tasks when short delays are introduced, however,  
452 when they have to match the global configuration of the stimuli their MTS ability is  
453 compromised by delays of 1.0 sec or longer. In more detail, we used an MTS condition  
454 in which the sample was available on the screen during the entire trial (SMTS) and five  
455 conditions in which the sample disappeared and the comparison stimuli appeared after  
456 0.0, 0.5, 1.0, 2.0 or 3.0 sec (DMTS). We found that capuchins' matching accuracy for  
457 local features was above chance level in conditions of up to 3.0 sec delay. Accuracy for  
458 global configurations was less robust. It was above chance level only in simultaneous,  
459 0.0 and 0.5 sec delay conditions. These findings suggest that capuchin monkeys could  
460 have a more accurate short-term retention of the local features of visual patterns than  
461 their global configurations. The extent to which this is due to a less effective encoding of  
462 global information or to a more rapid decay of information pertaining to the global level  
463 of stimulus structure in this species would need to be determined with further  
464 investigations.

465 We did not find a significant Level of processing x Delay interaction. In fact,  
466 increasing the delay induced a decrement in accuracy level in both local and global trials.  
467 In particular, in the global trials it decreased to chance level when the delay was of 1.0  
468 second or more. This happened contrary to the expectation that increasing delays could  
469 have provided an incentive to retain the global structure of the stimuli that allegedly  
470 supports a more economic storage of information (Navon, 1977). The local advantage in  
471 capuchin monkeys persists also for delay durations above 2.0 sec that have been shown  
472 to induce visual illusions and the processing of relationships between parts (Milner &  
473 Goodale, 2006). This suggests that the local advantage observed in simultaneous and

474 zero-delay conditions in capuchin monkeys cannot be explained by a selective  
475 engagement of the dorsal visual system induced by fast responding to stimuli that are  
476 perceptually available when acting upon them. Of particular relevance for this study are  
477 previous data by Truppa et al. (2014) showing that, when matching conditions identical  
478 to those of the present study were presented using non-hierarchical stimuli, capuchins  
479 were able to solve the task with up to 3 sec delay. Therefore, it seems that the encoding  
480 or the retention of the global properties of visual patterns is particularly vulnerable in  
481 capuchin monkeys. Capuchins can process the global aspects of stimuli, as shown here  
482 and in previous studies (De Lillo et al., 2011, 2012; Spinozzi et al., 2003, 2006).  
483 However, the results of this study show that global information is either encoded less  
484 accurately or deteriorates more rapidly in memory than local information. We cannot  
485 disambiguate these different scenarios in the present study. Nevertheless, it would be an  
486 interesting issue to address in further research.

487       The procedure we adopted in this study left the monkeys free to devote as much time  
488 as they wanted to the visual inspection of the sample. In fact, (i) in our SMTS condition  
489 the sample remained on the screen until the subject chose one of the comparison stimuli,  
490 and (ii) in our DMTS conditions, the sample remained on the screen until the subject  
491 touched it. It has been shown that increasing the duration of the sample presentation in  
492 MTS tasks does not improve monkeys' performance (D'Amato & Worsham, 1972)  
493 unless the subjects are required to repeatedly touch the sample stimulus before making a  
494 choice (Katz, Wright & Bachevalier, 2002). Therefore, it would be of interest to assess in  
495 future studies if by adopting the same procedure of Katz et al. (2002) it is possible to  
496 improve capuchins' MTS performance, especially when a more demanding condition,  
497 such as the processing of global properties, is required.

498 The order of presentation of the global and local trials differently affected capuchins'  
499 accuracy as a function of the delay condition (simultaneous, 0.0, 0.5, 1.0, 2.0 and 3.0 sec  
500 delay). When global and local trials were presented in blocked sessions the accuracy in  
501 simultaneous, 0.0, 0.5, 1.0 and 2.0 sec delay conditions did not differ from each other,  
502 whereas accuracy in 0.0, 0.5 and 1.0 sec delay conditions was significantly higher than  
503 those in the 3.0 sec delay condition; moreover level of response accuracy of the 2.0 and  
504 3.0 sec delay conditions did not differ. Differently, when global and local trials were  
505 intermixed in the same session the mean percentage of correct responses observed in  
506 simultaneous, 0.0 and 0.5 sec delay conditions did not differ from each other, whereas  
507 the accuracy level in all these conditions was significantly above the accuracy level  
508 observed with 1.0, 2.0 and 3.0 sec delays; moreover, the level of response accuracy of  
509 the 1.0, 2.0 and 3.0 sec delay conditions did not differ from each other. Overall, our  
510 findings indicated that blocked sessions induced a similar trend to that observed by  
511 Truppa et al. (2014) in capuchins tested with non-hierarchical stimuli. In that study, the  
512 response accuracy did not decrease for intervals up to 1.0 sec and a deterioration of  
513 performance occurred at the 2.0 sec interval. By contrast, in intermixed sessions, the  
514 drop in accuracy occurred earlier. In fact, response accuracy in the intermixed sessions  
515 remained at similar level for intervals up to 0.5 sec and a drop in performance was  
516 observed at 1 sec interval. This may have been due to the potential requirement of having  
517 to repeatedly shift attention between the two levels of stimulus structure in the  
518 intermixed sessions.

519 Moreover, the order of presentation of the global and local trials in the experimental  
520 sessions (intermixed or blocked) affected capuchins' response accuracy in a different  
521 way depending on the level of processing (global or local). Whereas in global trials there  
522 was no difference between the two types of presentation, counterintuitively, in local trials

523 the percentage of correct responses was significantly higher when global and local trials  
524 were intermixed than when they were blocked. In the present study, six intermixed  
525 sessions including 50% global trials and 50% local trials were alternated with six  
526 blocked sessions, three involving 100% global trials and three involving 100% local  
527 trials. Thus, the percentages of the two different types of trials varied always in an  
528 unpredictable way across experimental sessions. The reason why these variations  
529 affected local but not global response accuracy remains an unexplained phenomenon.  
530 Different results emerged when the proportion of trials requiring global and local  
531 processing are varied systematically to induce attentional biases. Using a simultaneous  
532 matching-to-sample task with the same monkey species, De Lillo et al. (2011)  
533 demonstrated that systematic variations of the proportion of global and local trials could  
534 reverse capuchins' preference. These authors showed a local advantage in the local bias  
535 condition (i.e., 85.7% local trials, 14.3% global trials) but a global advantage in the  
536 global bias condition (i.e., 85.7% global trials, 14.3% local trials). In the study by De  
537 Lillo et al. (2011), in fact, capuchins received a total of 16 experimental sessions with  
538 global bias and local bias conditions that were regularly alternated every 4 sessions.

539 The larger version of the stimuli used in this study (i.e., Set A) subtended  $14.9^\circ$  of  
540 visual angle whereas the smaller version (i.e., Set B) subtended  $7.59^\circ$  of visual angle.  
541 Whereas the level of accuracy was significantly higher in local than global trials with  
542 larger stimuli, the opposite pattern was not found with smaller stimuli. Specifically, by  
543 halving the size of our larger stimuli, the local preference of capuchin monkeys  
544 decreased but was not reversed. Effects ascribable to stimulus size have been also found  
545 in the human visual cognition literature. Studies in humans demonstrated that  
546 manipulations of stimulus size can reverse the global advantage in humans (Kinchla &  
547 Wolfe, 1979; Lamb & Robertson, 1988). For example, Kinchla and Wolfe (1979)

548 varying the stimulus from 4.8° to 22.1° of visual angle, found that human subjects had a  
549 global preference for patterns subtending less than 6° to 9° of visual angle, but a local  
550 preference for larger patterns. Thus, whereas in humans there is evidence that the  
551 stimulus size can produce a reversal of the global advantage, capuchins' strong local  
552 advantage shown with larger stimuli was decreased but was not reversed by a reduction  
553 of stimulus size. This result, indicates that variations of stimulus size do not seem to be  
554 sufficiently powerful to produce a global advantage in this monkey species, at least  
555 within the range of size variation considered in this study. Moreover, our results  
556 corroborate findings from other studies in non-human species which did not find a  
557 reversal of local (Spinozzi et al., 2006) or global (Truppa, Sovrano et al., 2010)  
558 preference, albeit with methodological procedures that did not allow to precisely control  
559 the visual angle subtended by the stimulus during the course of the trials. For example, in  
560 the study by Spinozzi et al. (2006) capuchin monkeys at the beginning of each trial  
561 viewed the stimuli mounted on a panel from approximately 30 cm, then the panel was  
562 brought closer to the cage (about 15 cm), within reach of the monkey's arm. Similarly,  
563 the experimental procedure adopted by Truppa, Sovrano et al. (2010) to test fish did not  
564 allow a strict control of the distance between the subject and the stimuli to discriminate  
565 since the fish was free to swim inside the experimental apparatus and to explore the  
566 stimuli visually from different distances before making a choice.

567 Finally, when RTs were considered, a significant main effect of the delay condition  
568 emerged indicating that, when the sample disappeared from the screen, the increase of  
569 the delay intervals led to significantly longer RTs, especially when 1.0, 2.0 and 3.0 sec of  
570 delay were introduced. This suggests that the increase in RT in DMTS can be indicative  
571 of an increased difficulty of retrieval processes when the memory trace starts to decay.  
572 Such a significant increase of the response time for delay intervals equal or longer than

573 1.0 sec has also been documented in capuchins (Truppa et al., 2014) and baboons  
574 (Rodriguez, Zvrcher, Bartlett, Nathanielsza, & Nijlanda, 2011) when brief delay intervals  
575 and non-hierarchical stimuli were used in DMTS tasks.

576 Overall, our findings indicate that the local advantage in capuchins is a very robust  
577 phenomenon and that it persists even when a delay is imposed between the presentation  
578 of the sample and the comparison stimuli. Thus, this study provides important additional  
579 information regarding the way in which monkeys encode global and local visual  
580 information in short-term visual memory. We hope that this evidence will encourage  
581 further detailed investigations on both attention and visual memory storage mechanisms  
582 in primate as well as other taxonomic groups. Future studies in human and non-human  
583 species would need to characterise the effect of memory load on the processing of global  
584 and local level of the hierarchical patterns, both when short- and long-memory systems  
585 are involved.

586

## Figure captions

**Figure 1.** (A) Experimental apparatus and stimuli presentation in the Simultaneous matching-to-sample condition (redrawn from Truppa et al., 2014); (B) Set of stimuli used in the experiment.

**Figure 2.** Mean percentage of correct responses performed by the monkeys in the Local and Global trials as a function of the different matching conditions (Simultaneous, 0.0, 0.5, 1.0, 2.0, 3.0 sec delay), (One-sample t-test: \*  $p < 0.05$ , \*\*  $p < 0.01$ , \*\*\*  $p < 0.001$ ). Error bars represent 95% confidence interval.

**Figure 3.** Mean percentage of correct responses performed by the monkeys in the simultaneous and the five delay (0.0, 0.5, 1.0, 2.0, 3.0 sec) conditions as a function of the order of trials. Error bars represent 95% confidence interval.

**Figure 4.** Mean percentage of correct responses performed by the monkeys in the Local and Global trials as a function of the order of trials. Error bars represent 95% confidence interval.

**Figure 5.** Mean percentage of correct responses performed by the monkeys in the Global and Local trials as a function of the stimulus size. Error bars represent 95% confidence interval.
